The Possibility of Spontaneous Generation of Charge.—The possibility of a spontaneous generation of charge within the earth was first tentatively suggested by G. C. Simpson (1916). This possibility has been elaborated by W. F. G. Swann (1927) into a theory in which a modification of the ordinary laws of electromagnetism is made in a form consistent with the theory of relativity and of such a type as to secure a slow death of positive charge as a result of the earth's rotation. The surplus negative electricity accumulates until it has built up a potential gradient adequate to drive negative electricity away from the earth at a rate sufficient to balance the rate of death of positive electricity. The necessary rate of death of positive electricity is very small. It amounts to only one proton per cu.cm. per *day*, or, in other words, it corresponds to a diminution of only 0·5% of the earth's mass in 10^{20} years. The modification in the electrodynamic scheme is also made to provide for the origin of the earth's magnetism and gravitation.

THUNDERSTORMS AND RELATED PHENOMENA

The first observations on the charge carried down by rain were made by Elster and Geitel (1899) and by H. Gerdien (1903), and led to the conclusion that more negative than positive electricity was precipitated by this cause. However, G. C. Simpson (1909), in a long series of measurements made at Simla, India, concluded that a much larger precipitation of positive than of negative occurs, and his conclusions have been supported by many observers in various parts of the world. The currents carried to ground by rain are usually of the order 10^{-12} amperes per sq.cm., and the amount of electricity per cu.cm. of the precipitated water is usually less than one electrostatic unit.

Thunderstorms.—It is a universally accepted belief that thunderstorms and lightning are a secondary phenomena brought about by the abnormal meteorological conditions we always find associated with them, and nearly all theories of thunderstorms invoke some mechanism by which falling rain drops, snow or hail become charged in some manner with one sign of electricity, while the air and smaller drops capable of being carried up by the rising columns of air associated with the storm are charged in the opposite sense. The separation of electricity proceeds until differences of potential are produced sufficient to result in a lightning flash.

According to one of the earliest theories, that of Elster and Geitel (1885, 1913), the rain drops were polarized by the potential gradient, so that they became positively charged below and negatively charged above. The smaller spray associated with the rain, and which is carried up in the rising air currents, was supposed to strike the larger descending drops on the underside and remove from them some of the positive charge, so that they fell to earth negatively charged, while the smaller drops were carried upwards with the positive charge. On this view the electrical separation would act to increase the electric field formerly existing, a result not in harmony with the usual facts. There is a certain amount of evidence that the smaller drops may rebound from the larger drops in such a way as to part from them at the top; and on such a view the possibility of positive precipitation becomes realized. However, the theory has suffered criticism in connection with the possibility of the existence of the necessary contact between drops at the moment of rebound to secure a separation of charge without a coalescence of the drops.

G. C. Simpson's theory rests upon the experimental fact that, when falling water drops are caused to break on a rising stream of air, the water drops become positively charged while the air or lighter spray becomes negatively charged. In the period immediately preceding the thunderstorm we picture a sort of hourglass structure to the air motion, in the vicinity of the thundercloud, the air feeding in towards the axis of the hour-glass below, then rising vertically and finally fanning out at the top. As the

air rises into colder regions precipitation forms and the drops grow as they fall. However, it is contended that drops large enough to fall in air which is rising with a velocity up to 8 metres per second become unstable and break up into fine drops. In this process they become positively charged while the air around them is negatively charged. It is thus contended that when the drops in their fall reach the narrowest part of the hour-glass where the velocity is high, they break up and become positively charged. Having been reduced in size by the disruption, they start to rise in the air current, but not as fast as the negatively charged air. As they rise they start to coalesce on account of their charge, and eventually attain such a size that they once more start to descend. The process continues, and as it does so the rain becomes charged more and more positively at each successive descent, while the rising air carries negative electricity to the top of the thundercloud. Eventually the potentials attained become sufficiently high to result in a flash between the top and bottom of the cloud, or occasionally between one part of the cloud and another. On Simpson's views, the rain which falls in the centre of the thundercloud should be positively charged, while a negative charge should appear on the rain which falls from the more remote regions and has received its charge from the negatively charged air which has risen to the top of the cloud and fanned out at the sides.

Simpson's theory does not lead immediately in its details to an explanation of the origin of lightning flashes in cases where all the water concerned is in the form of ice. However, H. Norinder has shown that large separations of charges may be produced by the impact of ice particles with each other, the small particles becoming charged with a sign opposite to that which the larger particles acquire. Again, a separation of the two comes about through the greater supporting power of the rising currents for the smaller as compared with the larger particles.

The Electron Currents and Fields Developed in Lightning Flashes and Thunderstorms.—By measuring the changes of electrical potential of an exposed insulated conductor, C. T. R. Wilson (1920), H. Norinder and others have made estimates of the electric fields associated with thunderstorms, and from these have deduced the orders of magnitude of the charges on thunderclouds, and the amount of electricity transferred when a lightning flash takes place. Estimates of the last named quantity have also been made in a novel manner by W. J. Humphreys from an estimation of the pinch effect produced in a lightning rod which had been struck and crushed by the attraction of the current elements on each other during the discharge.

The fields developed at the earth's surface in the vicinity of thunderclouds are of the order of 100,000 volts per metre, and an average lightning flash may discharge about 20 coulombs through a length of two kilometres.

Data collected by the British Meteorological Office show that at any one time about 1,800 thunderstorms are in progress in different parts of the world, and that the average frequency of lightning flashes during a storm is about 200 per hour. This gives about 100 flashes per second as representative of the average frequency of lightning discharges for the whole earth.

Special Forms of Lightning.—It has been supposed by W. J. Humphreys that a lightning flash progresses by a sort of burrowing action rather than by a simultaneous breakdown of the whole lightning part. Humphreys supposes that at any instant during the formation of the flash the field at the end of the lightning streak ionizes the air immediately around it, permitting of its further extension, and so on until the flash is completed. While there is some doubt as to the universality of this origin of the flash, the process undoubtedly occurs in certain instances, and to special forms of this type of development Humphreys has attributed the occurrence of *rocket lightning* and *ball lightning*. The former is seen as a progressive burrowing of the flash through the sky and is to be attributed to conditions in which the flash grows at a slow rather than at its customary rapid rate. *Ball lightning*, in which a ball of fire may be seen to hang in the sky, may be regarded as a form of rocket lightning in which the progress of the flash is very slow and the conditions are such that the ionization at the end of the discharge is just able to maintain itself. *Sheet lightning* is merely the reflection of ordinary lightning from the clouds. Some observers have reported the appearance of discontinuous or beaded streaks of lightning. It has been suggested that they arise from successive discharges and that each bead may represent the end-on view of the irregular portions of the lightning path; these remain luminous during the subsequent lesser discharges, while the intermediate sections become non-luminous because viewed from the side. *St. Elmo's fire* is simply a brush discharge from objects projecting from the earth's surface and it is caused by intense fields resulting from the presence of thunderclouds.

ELECTRICITY, CONDUCTION OF. The mechanism of the conduction of electricity is markedly different in solids, liquids and gases, which are accordingly dealt with separately.

CONDUCTION IN SOLIDS

The electric conductivity of a substance is that property in which electricity is transferred through the substance if an electric potential difference is applied to two parts thereof. A substance in which unit quantity of electricity is transferred through unit cross-section under the influence of unit potential gradient is said to have unit conductivity. The reciprocal quantity is the electric resistance which may be defined in a similar way. A priori the quantity of electricity transferred for a given potential gradient might well depend upon how long the current had been flowing. The concepts, electrical conductivity and electrical resistance, would probably never have been formed were it not that there is a large class of substances for which the conductivity is determined completely by the conditions of the moment and is independent of the previous history of the conductor. Strictly speaking, it is for these only that the terms conductivity and resistance have any validity. All substances conduct electricity to a greater or smaller degree. For the purpose of description, it is convenient to divide solids into three classes, namely, metallic conductors, non-metallic conductors and dielectrics although there are no precise lines of demarcation.

Metallic Conductors.—The main characteristics of a metal are its high electric conductivity and consequent opacity, its good heat conductivity, its tendency to form positive ions in solution and its inability to form a simple solution in non-metals. All these properties are consequences of the ease with which the atoms of a metal can lose or dissociate electrons. When in the vapour phase the atoms are far apart and electrons dissociate appreciably only at comparatively high temperatures such as the surface of the sun or stars. But when the atoms are packed close together as in solid metals, polarization comes into play so that it is easier for an electron to escape from its parent atom. That the current is carried through a metal by these free electrons has been proved. That they can also transfer heat is an extremely important phenomenon, the explanation of which is not so apparent.

Resistivity of Metallic Conductors.—The resistance of a

conductor depends of course upon its shape as well as upon the material of which it is composed. The effect of shape can be eliminated and the specific resistance of the material, *i.e.*, the resistance of unit cube, can be obtained provided Ohm's Law, that the current is proportional to the applied voltage, and inversely proportional to the resistance, is satisfied. In metals, Ohm's Law is fulfilled to a very high degree of accuracy; slight deviations have, however, been found at excessively high current densities. If a current of the order five million amperes per square centimetre is made to flow through a thin film of silver or gold, the departure from Ohm's Law may amount to something of the order of one per cent. Strictly speaking therefore, the definition of the specific resistance should include the current density, but in metals at any rate, Ohm's Law is valid over such an enormous range that this can be omitted. If a conductor is of uniform cross-section and of homogeneous material, the potential gradient must be uniform, since the current flowing through every cross-section must clearly be the same. It has been shown that the resistance of such conductors is inversely proportional to their cross-sections. Hence, in this simple case, it is easy to derive the specific resistance from the resistance of the conductor. It is obviously the observed resistance divided by the length in centimetres and multiplied by the cross-section in square centimetres. Thus, a wire one metre long and of a cross-section of one square millimetre, will have a resistance 10,000 times greater than the specific resistance of the material of which it is composed, or inversely, the specific resistance of the material is one ten-thousandth of the observed resistance of such a wire. If the shape is not so simple, the transition from observed resistance to specific resistance is, of course, much more complicated, since the potential gradient will vary along the conductor. The resistance of a metallic conductor is within wide limits independent of the time. It has been shown that the reflection coefficient of metals for infra-red rays may be calculated from the resistance if one treats the incident radiation as an alternating field as postulated by the electro-magnetic theory. That this relation breaks down at frequences of the order 10^{14}, *i.e.*, for currents which change their direction in 10^{-14} seconds, is scarcely surprising. It indicates merely, that the resistance to the motion of the electrons is composed of a number of elementary processes at intervals which are not short compared to 10^{-14} seconds.

International Ohm.—The practical unit of electrical resistance was legally defined in Great Britain by the authority of the Queen in council in 1894, as the "resistance offered to an invariable electric current by a column of mercury at the temperature of melting ice, 14·4521 grammes in mass, of a constant cross-sectional area, and a length 106·3 centimetres." The same unit has been also legalized as a standard in France, Germany, and the United States and is denominated the "International or Standard Ohm." It is intended to represent as nearly as possible a resistance equal to 10^9 absolute C.G.S. units of electrical resistance. Convenient sub-divisions and multiples of the Ohm, are the microhm and the megohm, the former being a millionth part of an Ohm, and the latter a million Ohms. The resistivity of substances is then numerically expressed by stating the resistance of one cubic centimetre of the substance taken between opposed faces, and expressed in Ohms, microhms or megohms, as may be most convenient. The reciprocal of the Ohm is called the Mho, which is the unit of conductivity, and is defined as the conductivity of a substance whose resistance is one Ohm. The absolute unit of conductivity is the conductivity of a substance whose resistivity is one absolute C.G.S. unit, or one-thousandth-millionth part of an Ohm.

Besides this so-called volume-resistivity, a quantity is sometimes employed, called the mass-resistivity, defined as the resistance in ohms of a wire of the material in question of uniform cross-section one metre in length, and one gramme in weight. This quantity is of small scientific interest, though convenient in some cases for technical purposes when the weight of a conductor, capable of carrying a given current at a given voltage, is of importance. The mass-resistivity so defined, is the volume-resistivity multiplied by the density times 10^4.

A quantity of far greater importance, for the understanding of the cause of metallic resistance, may be described as the atomic-resistivity. Since one is only concerned with comparative quantities the units are of course immaterial, but it might be conveniently described as the resistance for unit potential difference of a cube containing Avogadro's number of atoms. This quantity refers to the electrical characteristics of the metal in comparable circumstances, *i.e.*, there are the same number of atoms in cross-section in each case, and the potential drop per atom is the same. It may be obtained from the usual volume-resistivity, by multiplying by the third root of the density and dividing by the third root of the atomic weight. Table I. gives a list of the commoner metals with their volume-resistivity, mass-resistivity and atomic-resistivity at 18° C. The values are given in ohms: they can be translated into absolute C.G.S. units by multiplying by 10^9.

TABLE I.

Metals	Volume resistivity at 18° C $\times 10^{-6}$ ohms	Temp. coeff. of volume resistivity 0°–100° C $\times 10^{-4}$	Mass resistivity at 18° C ohms	Atomic resistivity at 18° C $\times 10^{-6}$ ohms	Atomic resistivity at corresponding temperatures $\times 10^{-6}$ ohms
Aluminium	2·94	38	0·079	1·36	1·8

NOTE: The resistance of a metal varies according to its previous history, *i.e.*, whether it has been rolled, drawn, cast, etc., and also according to its purity, a small trace of impurity in many cases increasing the resistance by 20%. Therefore in actual practice variations of 10% in the above values may be expected.

*0°–24° C. †0° C—melting point.

The figures of course refer to normal polycrystalline metals. Single crystals may have a higher conductivity, *e.g.*, in copper there is a difference of about 8%. In non-cubic crystals the conductivity also varies with the orientation, as will be seen a most important and suggestive phenomenon. It will be noted that the volume-resistivity of the metals in the first group of the periodic table, is lower than that of any of the others. The transition elements, like bismuth and antimony, have an abnormally high resistance, but no clear connection between the resistivity and the other characteristics of the metals is immediately discoverable. This can scarcely cause surprise, since the metals are not in comparable condition as regards temperature. Comparable temperatures, according to modern theories of specific heat, would be those in which the amplitudes of oscillation of the atoms, were in all cases an equal fraction of the distance between them. If the atomic-resistivity is reduced to corresponding temperatures, as exhibited in the last column of the table, one sees a certain regularity emerge.

So far attention has been directed exclusively to pure metals. The resistance of alloys is a very complicated matter. In the case of those alloys, which do not form solid solutions and which consist really simply of a mixture of two or more metals, the specific conductivity, as might be expected, is proportional to the volume composition of the alloy. The conductor is merely an aggregate of small conductors consisting of pure metals. The resistivity is a much more complicated matter in those cases, in which one metal is in solid solution, in the other, *i.e.*, in which the crystal structure is retained, and the atoms of one metal are replaced by atoms of the other in the space-lattice. The admixture of the second component raises the resistivity, and if the two metals form a continuous solid solution, one finds in general in a binary alloy a continuous curve rising fairly sharply at either end of the scale with a flat maximum between the two pure metals. The effect of different metals upon the electrical resistance is very varied. Thus the addition of 1% of silver to copper, changes its resistivity by an amount variously estimated at 7 to 12 per cent, whereas one percent of zinc changes it by 15 to 17, tin 145, chromium 220 and antimony 310 to 420 per cent. In general it would seem that the effect is greater the further the solvent and solute metals are apart in the periodic table, but this can only be regarded as an empirical rule which may have a certain technical interest when the effect of impurities is at issue.

Temperature.—One of the most important factors affecting the electrical resistance is the temperature. If one plots the resistance of a pure metal as a function of the temperature, it may be represented roughly as a straight line pointed at the origin, in other words, the resistance may be represented as a very rough approximation, by the expression const. T. This significant fact is only the first which emerges. A closer examination reveals that this expression is only a first approximation and represented more accurately by the expression const.U,U representing the internal energy of the metal. The internal energy is the integral of the atomic heat, so that if this formula were accurate the temperature coefficient of the resistance should be proportional to the atomic heat. It has been shown that the atomic heats of the elements, which according to Dulong and Petit's law, should be constant and equal to about six calories, may in reality be represented with much more accuracy by a complicated, but general function of the temperature divided by a characteristic temperature pertaining to each individual metal. (*See* QUANTUM THEORY.) At high temperatures this function approaches asymptotically the value 3 R demanded by Dulong and Petit. At temperatures of the order of the characteristic temperature, the atomic heat falls well below 3 R and approaches zero as the absolute zero of temperature is reached. Metals with a high melting point, *i.e.*, strong inter-atomic forces and low atomic weights, such as aluminium or copper, have comparatively high characteristic temperatures, whilst metals with a low melting point and large atomic weights, such as lead or mercury have low characteristic temperatures. Thus in the first class, the atomic heat falls considerably below 3 R at comparatively high temperatures (100° to 200° absolute) whilst in the latter class the atomic heat remains constant down to much lower temperatures (20° to 40° absolute). The temperature coefficient of the resistance shows the same characteristics. Constant, in the case of copper and aluminium down to 100° to 200° absolute, at these temperatures it commences to fall whereas, in the case of lead or mercury it remains constant down to 20 or 40 degrees of the absolute zero. This very striking fact is often masked by the presence of slight impurities. As was pointed out above, these usually have the effect of increasing the resistance. The added resistance due to the impurity, is not subject in the same way to the effect of temperature. As a first approximation, it may be treated as a constant so that the resistance of a metal may be represented roughly as composed of two terms, one small and constant, probably due to the presence of impurities, and the other rising according to the universal function of the temperature, which presents the internal energy of the metal.

The fact that the added resistance due to the alloying metals does not vary greatly with the temperature, has been made use of by employing alloys of special composition for standards of resistance and other similar purposes. When the main resistance is the alloy resistance, as for instance occurs when the metals which conduct well individually, are dissolved in one another, the constant term is large compared to the term which represents the resistance as a function to the temperature and the total resistance may be almost independent of temperature.

A very remarkable phenomenon has been observed in the case of some metals whose resistance has been measured at extremely low temperatures. Observed to be normal down to the vicinity of about 5° absolute, the resistance already small, but easily measurable, diminishes suddenly to an imperceptible quantity. In the case of lead for instance, it has been shown that the resistance below the critical temperature is less than 10^{-12} of its value at zero centigrade. So small is the resistance in this state, that a current started in a ring, induced say by removing a magnet from the centre, will continue to flow for months without appreciable diminution. This so-called supra-conductivity is a quite distinct phenomenon which has only been observed in the case of certain metals. At first sight, it might appear that its absence in the case of other metals might be due to some small impurity, which gives the metal a small alloy resistance unaffected by temperature. This does not seem to be the true explanation, for supra-conductivity has been looked for in vain in gold which can be obtained relatively pure, whilst it has been found in such metals as tin and lead which are much more likely to contain traces of impurities. Table II. gives a list of those metals in which supra-conductivity has been observed and the temperatures at which it appears.

TABLE II.

Substance	Temperature at which supra-conductivity appears
Indium	3·40° Abs.
Tin	3·72° ,,
Mercury	4·16° ,,
Thallium	2·47° ,,
Lead	7·20° ,,

A most important fact that emerges is that supra-conductivity sets in at an extremely well marked and definite temperature. It can be destroyed by the application of an external magnetic field to reappear as the temperature is lowered; this is not altogether surprising seeing that an electrical current must be due to the motion of electric charges, when one considers the curvature of the path of a moving charge produced by a magnetic field.

Pressure.—The effect of pressure upon the electrical resistance of metals is usually slight. In a great majority of cases it diminishes the resistance, but in a few, namely, Lithium, Caesium, Calcium, Strontium, Antimony and Bismuth, the resistance increases as the pressure is raised. Caesium occupies a special position as the only metal in which the resistance first increases and afterwards decreases with rising pressure, a condition which has been sought, but not found in any other metal. At first sight it might seem surprising that an increase of pressure which corresponds to a decrease in volume, should facilitate the flow of electrons through the metal. Even taking into account that the specific resistance is the resistance of unit volume, so that the increase of pressure with the accompanying contraction corresponds to an increase in the number of atoms and therefore, of electrons in unit volume, the conductivity often increases. Since one has an effect compounded of the variation in the permeability of the metal for electricity and the change in the number of electrons in unit volume owing to the increase in density, simple results can scarcely be expected. The effects are in all cases small, being of the order of the change in volume, *i.e.*, the fractional change of resistance is of the order 10^{-12} or 10^{-11} per dyne.

Stress.—Still more complicated are the effects of stress and deformation on the electrical resistance. These are of a similar order of magnitude to those due to pressure as long as the

deformations are within the elastic limit. When greater deformations are produced, considerably greater changes are caused and variations up to as much as 8% have been observed on working some of the pure metals. The same applies to the temperature coefficients, but all these effects may be annulled by annealing the metal, when recrystallization takes place and it returns to its original unstrained condition.

Magnetic Field.—The effect of a magnetic field upon the conductivity of a metal shows itself in various ways. The so-called longitudinal Hall effect, is the name given to the change in the resistance which occurs in the magnetic field. For all except magnetic metals (iron, nickel and cobalt) the resistance increases, the amount however, being of the order of ·01% for a field of ten thousand C.G.S. units. In bismuth a comparatively enormous effect is observed, so much so, that the resistance of spirals of thin metal bismuth wire is used for measuring magnetic fields. The order of magnitude of the effect is shown in table III., and it will be noted that it increases very much at low temperatures. It is probable that this effect is a secondary one, due to the presence of microscopic cracks which expand under the influence of the field.

TABLE III.

Field strength	Resistance of bismuth in magnetic field	
	Temp. 19° C	Temp. 185° C
0	116,200	41,000
8,800	149,200	738,000
21,800	257,000	6,190,000

Allied Effects.—Four lateral effects caused by the magnetic field correspond to the lateral displacement of a moving electrical charge. The *Hall* effect may be described as the potential difference produced on the two edges of an elongated metallic plate through which a current is flowing when placed in a magnetic field at right angles to it. The magnitude varies from metal to metal, and is in general small, but no relation has as yet been discovered which enables one to predict either its magnitude or even its sign.

The *Ettinghausen* effect is the name given to the temperature difference produced on the two edges on an elongated metal plate through which a current is flowing by the application of a magnetic field at right angles to it. It analogizes to the Hall effect, except that a temperature difference is observed in place of a potential difference.

The two other transverse effects correspond to the above, except that a current of heat replaces the electric current. The *Nernst* effect expresses the fact that a potential difference is observed between the edges of an elongated plate down which heat is flowing when it is placed in a magnetic field. The *Righi-Leduc* effect corresponds to the temperature difference observed on the edges in similar circumstances. All these effects are very slight in the case of the normal metals, but are much greater in the case of elements such as antimony and bismuth, in which non-metallic properties begin to appear.

Thermo-electric (or Seebeck) Effect, Peltier Effect and Thompson Effect.—One cannot consider the electric conductivity of metal without taking into account secondary effects connected with the mechanism by which electricity is transported from one part to another. The best known of these, is the thermo-electric effect, also well known as the Seebeck effect. If two different metals are brought into electrical contact at two points, thus forming a circuit, and the two junctions are kept at different temperatures, a current flows round the circuit. The voltage difference for any given pair of metals, depends solely upon the two temperatures, the current of course being determined by this voltage difference and the resistance of the circuit. At any given temperature the metals may be arranged in a definite order according to the potential difference, which is produced with a given temperature difference between each metal and any one of them arbitrarily chosen as the zero. The potential difference produced by forming a circuit between any two of them is then simply the difference between the voltages produced against the standard metal. Table IV. gives a list of the commoner metals and the potential differences produced against platinum for a temperature difference of one degree centigrade at 0° C. It is evident that these thermo-electric constants are small, usually less than 10^{-4} volts per degree. Their magnitude depends upon the temperature, becoming smaller as the absolute zero is approached. Small though they are the thermo-electric effect forms the basis of a large class of instruments for measuring temperature. It is evident from what has been said, that all that is required is to solder or weld wires of two metals together and measure the voltage difference between the two other ends when the junction is brought to the temperature it is desired to measure.

TABLE IV.

Metal	Thermo-electric effect against platinum at 0° C for 1° diff. in temp.$\times 10^{-6}$ volts
Aluminium	3·8
Antimony	47·0
Bismuth	−65·0
Copper	7·4
Iron	16·0
Palladium	− 5·6
Silver	7·1
Constantan	−34·4

An inversion of the thermo-electric effect is the *Peltier effect.* If two dissimilar metals are brought into electrical contact and a current is passed through the junction this is heated or cooled according to the direction of the current The amount of heating or cooling for a given current at a given temperature depends solely upon the metals used.

The Thompson effect is of somewhat similar character. If a current is passed through a metal, parts of which are at different temperatures, a certain transport of heat takes place, whose amount depends upon the strength of the current. A very important property possessed by all good electrical conductors is the faculty of transmitting heat. Thermal conductivity is possessed in a greater or less degree by all substances. It is measured by the quantity of heat transferred across unit cross-section in unit time for unit temperature gradient. In solids we may distinguish three different types of thermal conductivity. Amorphous solids such as glass possess a conductivity, usually small, which does not vary greatly with temperature. Crystals such as rock salt or rock crystal possess a conductivity roughly inversely proportional to the temperature. At ordinary temperatures it is usually of the same order as the amorphous conductivity of a glass, but at low temperatures clearly it may and does become large. The expression low and high temperatures refers of course to the characteristic temperature of the substance, familiar from the theory of the specific heats.

Electrical conductors possess in addition a thermal conductivity, which would in a non-conductor be considered large and which does not vary greatly with temperature. The mechanism which enables heat to be transported in conductors is certainly closely allied to that which comes into play in electrical conduction. This is shown by the fact that there is a very distinct proportionality between the electrical and the thermal conductivity of the metals. The so-called Wiedemann-Franz constant is the ratio of thermal to electrical conductivity. As shown by table V. it is approximately constant for a large number of metals, whose conductivities diverge by a factor of no less than 27. It will be noted that there is a steady increase in the constant as the conductivity decreases. This is in part due to the fact that the metals possess, in addition to electronic conductivity, the ordinary atomic conductivity of every solid. It is clear that this will become more important as the electronic conductivity diminishes. Its amount may be estimated in the case of single crystals, where it is known that the atomic conductivity varies inversely as the temperature and a corrected Wiedemann-Franz constant can be obtained by subtracting the atomic conductivity from the total conductivity and dividing the electronic conductivity, thus

TABLE V.

	Heat Conductivity / Electric Conductivity at 18 cent. $\times 10^{-8}$ e.m.u.	Temperature coefficient of Heat Conductivity / Electric Conductivity $\times 10^{-4}$
Theoretical	517	36·6

Manganine	912	25
Steel	890	36

obtained by the electrical conductivity. This is found, in the cases examined, to give a result even more constant than that obtained in the table. In the last column of the table may be found the temperature coefficient of the ratio of the conductivities. As will be seen, this is approximately ·36 per cent, *i.e.*, the Wiedemann constant appears to be proportional to the absolute temperature. This fact, which is usually regarded as of great importance in any theory of electrical conduction, is of course only another way of stating that the electrical conductivity is roughly inversely proportional to the temperature, whilst the thermal-conductivity is approximately constant. For any theory of electrical conductivity, an important factor is the specific heat of the substance. It has been shown that monatomic substance have atomic heats at constant volume, which may be represented with considerable accuracy by one and the same function of the temperature over a characteristic temperature. Measurements have shown that, at any rate at ordinary temperatures and at low temperatures, the metals possess atomic heats conforming accurately to this function. Reduced to corresponding temperatures, there is no perceptible difference between the atomic heat curve of a conductor and a simple non-conductor. The conclusion seems inevitable that the mechanism which transmits electricity and heat, and which distinguishes electrical conductors from non-conductors, possesses no appreciable heat capacity of its own. Such are the main characteristics of electrical conductors. It remains to consider the theories which have been advanced to account for them.

Theories of Electric Conduction in Metals.—Various attempts have been made to account for the properties of metallic conductors. The first, which for a time was widely accepted, may be described as the electron gas theory (Drude, Riecke, H. A. Lorentz). It was assumed that electrons dissociate from the metal atoms and exist in the interstices between them in much the same state as the atoms of a perfect gas would exist, say, in a heap of shot. According to the classical Kinetic Theory of Gases, the law of equipartition of energy would be fulfilled so that if m is the mass of the electron, k is Boltzmann's constant, and t the absolute temperature: its mean velocity v would be given by the equation $\frac{mv^2}{2}=\frac{3}{2}kT$. At ordinary temperatures, owing to the small mass of the electron, v is very large, of the order of 10^7 cm/sec. Any velocity which can be superposed by extraneous means, such as an electrical field, is negligible compared to this. Hence one may consider, according to this theory, the electrons to be flying about at high speeds until checked by collision with the atoms, their paths being slightly modified but not materially altered in length by any outside influence. If a field X be applied, the electron will suffer an acceleration $X\cdot\frac{e}{m}$, e being the charge. If t is the time between one collision and the next, the electron will acquire an extra velocity $\frac{Xe}{m}\cdot t$ during one free path. If there are n electrons in unit volume the field X will therefore cause a current $\frac{Xne^2}{2m}t$ to flow, in other words, the specific conductivity will be $\frac{ne^2}{2m}t$. In itself, this value is reasonably plausible. If the known figures for e and m are inserted and n is taken of the same order as the number of atoms per cubic centimetre t is of the order 10^{-15} which corresponds to a free path of 10^{-8} cm., the order of distance between the atoms. Without supplementary hypotheses however, it is not clear why the conductivity should vary inversely as the absolute temperature.

The thermal conductivity, according to this theory may, of course, be attributed to the same mechanism which causes a gas to transmit heat. It is merely the diffusion of the hotter and therefore swifter particles, into the more slowly moving ones and the transfer of heat from one group to the other. If ΔT is the temperature gradient, the amount of heat transferred according to the ordinary kinetic theory is $\frac{nv^2k}{2}t\cdot\Delta T$. Hence the conductivity is $\frac{nv^2k}{2}t$, $\frac{3k}{2}$ of course representing the heat capacity of the electron. This expression again gives rise to reasonable values.

The real triumph of the theory is manifest when the Wiedemann-Franz constant, the ratio of thermal to electric conductivity is formed. Inserting the two expressions, it is clear that the quantities n and t, *i.e.*, the number of electrons per cubic centimetre and the time between collisions (those quantities which might well be expected to vary from metal to metal), cancel out, leaving for the ratio of thermal to electrical conductivity $\frac{3k^2}{e^2}T$. Hence the theory explains why the ratio of thermal to electrical conductivity is the same in all conductors and also predicts that it should be proportional to the absolute temperature, as was found empirically. Not only does it give a qualitative explanation, but it gives a very fair approximation to the absolute value, if the known values of k and e are inserted.

The theory of course gives a qualitative explanation of the effect of a magnetic field, since this would cause the deflection of moving electrical particles, though the inverse magnetic effects require supplementary hypotheses; it also explains qualitatively the thermo-electrical, Peltier and Thompson effects, since the electron gases in two different metals would not in general have equal pressures, and, as in the case of osmotic cells (see *Solution*), one would always have a balance between the tendency to diffuse under the influence of thermal agitation and the potential differences set up as soon as movement of the electric charges take place.

The difficulty which proved fatal to this theory, is that it involves the assumption that the electrons have the atomic heat of a monatomic gas. Without this, one cannot obtain the Wiedemann-Franz constant, but if one makes this assumption then the metals should possess atomic heats considerably greater than the non-metals. Of this there is no trace. One cannot escape the dilemma by assuming that only a very small fraction of the atoms dissociate, for in this case thermodynamics shows that the number of electrons would vary rapidly with temperature becoming negligible at low temperatures just where the conductivity is greatest. Thus this theory, great as was the advance which it marked upon the previous attempts to explain the nature of metallic conduction, has had to be abandoned.

Numerous other theories have been put forward to account for the phenomena whilst avoiding this difficulty. One of the first (J. J. Thompson) endeavoured to resuscitate something akin to the Grotthus chain theory of electrolytes. The atoms were considered as dipoles and electric conduction was attributed to the transfer of electrons from one atom to the next. Under the influence of the field the dipoles would tend to arrange themselves, and the probability of an electron being pulled out of the negative part of one dipole into the positive part of the next, would be increased. If the dipoles are distributed at random, there will be no tendency for the electrons to flow in any definite direction,

it is only the polarisation on this theory which gives rise to the current. If one supposes that the kinetic energy of the electron in the doublet is proportional to the kinetic energy of the doublet, then of course a transfer of particles will involve the transfer of energy from hot to cold parts of the metal and give rise to heat conduction. This theory is incompatible with modern views and has scarcely more than historical interest. The mechanism of dissociation, the assumption that the kinetic energy of the electron equals that of the atom and values which emerge, if the figures are inserted in the formula, disprove its validity. It has been mentioned, chiefly because it may be regarded as the precursor of a theory which has been put forward much more recently by Bridgman. In this the electric current is attributed in the main to the flow of electrons inside the atoms, not to the motion of electrons between them. The hindrances to the free flow of electrons are found according to this theory, not in the atoms themselves, but in the gaps between the atoms. The theory was concerned chiefly to explain the increase in conductivity, usually observed under hydrostatic pressure. This, it need scarcely be said, is quite simple since pressure will tend to close the gaps between the atoms. The effect of temperature which causes expansion of the metal and raises the amplitude of the atomic vibrations is to increase the number of gaps and the resistance. Heat conduction is explained as partly electric and partly atomic though the share attributed to the atoms is far larger than one would normally expect. It seems probable that the somewhat crude assumptions which underlie it, and the additions which have become necessary in order to explain even such a fundamental quality as thermal conductivity, will militate against the acceptance of this hypothesis.

Various theories (Lindemann, Wien) were based upon the assumption that the free path of the electrons depends upon the amplitude of oscillation of the atoms. This explains at once why the resistance is proportional to the energy content of the solid, since pressure augments the forces between the atoms the frequency is increased and for a given energy, the amplitude diminished. From this point of view it is to be expected that an increase in pressure would lead to a decrease in resistance, since a decreased amplitude means an increased free path. Scarcely one of these theories progressed beyond the first tentative beginning, and none of them appear likely to survive. A theory of a totally different kind, put forward by Lindemann, endeavoured to reconcile the great heat conductivity of metals with the negligible heat capacity of the electron by treating these as forming a space-lattice, interleaved between the atomic lattice. As has been pointed out, a crystal at low temperatures conducts heat comparatively well, even though its atomic heat may be negligible. This fact, which had been plausibly explained by Debye, appears to suggest a simple mechanism for the transfer of heat in metals.

Electrons repel one another so strongly that the idea of an electron gas is almost a contradiction in terms, unless one attributes enormous velocities to the particles. At ordinary temperatures the equipartition energy would only suffice to make the particles quiver, if each atom in a solid had dissociated an electron. Under the influence of an electric field the electron space-lattice would move continuously through the atomic space-lattice, provided a source of the electrons were connected to one end of the conductor, and if the electrons were able to flow out at the other, *i.e.*, if the circuit were closed. In pure metals at extremely low temperature, it seems possible that the electron space-lattice might move almost unimpeded through the atomic space-lattice; with increasing temperature the amplitude of oscillation of the atoms increases and obstacles would be interposed to the space-lattice drift. In an impure metal a constant resistance would be superposed upon the resistance due to the thermal agitation, on account of the irregularities produced in the original atomic space-lattice by the foreign atoms embedded in it. The forces between the electrons, as was pointed out, would be of the same order as the forces between the atoms. Since the electron has a very small mass the proper frequency, and therefore the characteristic temperature of the electronic space-lattice would be extremely high, of the order of one hundred thousand degrees. Thus the heat capacity of the electrons would be negligible though, since they would form a crystal, they could conduct heat. All the minor effects can of course be explained on similar lines to those current in the theory which treats the electrons as forming a perfect gas. The main advantage which this theory possesses, besides avoiding the contradiction involved in attributing to a perfect gas, heat conductivity without heat capacity, is that it gives a plausible reason for the large increase of resistance, which may be caused by the admixture of a foreign element and also that it accounts for the fact that metal crystals may have different conductivities along different axes.

The most recent theory (Sommerfeld) treats the electrons as a completely degraded gas. It is difficult to go into this in any detail without a considerable digression upon wave mechanics and the modifications of statistical mechanics, imposed by what is usually called the quantum theory. It has been suggested by Pauli that no two electrons in an atom can have the same four quantum numbers. This simple rule explains the existence of the periodic system of the elements. The same rule was applied by Fermi to a gas. This leads at high temperatures to the ordinary laws. At low temperatures however, the gas would deviate considerably from the state predicted by the classical theory. At the absolute zero it would still exert a pressure and possess energy, for clearly since only one atom can have the four quantum numbers, all the other atoms must contain some energy. If one applies the formulae of this theory to the electrons in a metal, one finds a considerable measure of agreement with experimental fact. As in the classical electron gas theory, the number of electrons in unit volume and the time between collisions enters in the same way into the formulae for the electrical and thermal conductivities. Hence the Wiedemann-Franz constant emerges, and what is more, its absolute value agrees somewhat more closely with experiment than it does according to the classical theory. The heat capacity of the electrons is negligible, for their mass is so small that it only amounts to a fraction of one per cent of the heat capacity of the atoms. The exact meaning of the free path on this theory, is as yet perhaps not quite clear and special assumptions have to be made about it in order to explain the variation of a resistance with temperature. No obvious explanation is given for the large effect of impurities, nor does it seem easy on this theory, to account for a difference in conductivity along the different axes of a crystal. On the other hand, the fact that it is possible to obtain the Wiedemann-Franz constant without having to assume a large heat capacity, marks a notable advance.

Non-metallic Conductors.—Little accurate information is available about non-metallic conductors. Many of them exhibit departures from Ohm's Law and some of them are not even independent of the time in their electrical characteristics. Numerous specimens of various substances have been examined with considerable care, but the values found depend so much upon the treatment and form of the specimen, that no useful purpose would be served by a detailed description of the results. Thus for instance, carbon, one of the most carefully investigated substances, displays values of the conductivity according to its form, varying by as much as a factor three and if the allotropic modification, graphite is included, by as much as twenty to one. In general non-metallic conductors have a very much higher resistance than metallic conductors, carbon for instance, having a resistance two thousand times that of copper at ordinary temperatures. All of them have a negative temperature coefficient, *i.e.*, the resistance decreases with rise of temperature, unlike metals whose resistance, except for some curious alloys, invariably increases as the temperature is raised. At sufficiently high temperatures, there is in some cases a change in the sign of the temperature coefficient, but not sufficient evidence is available to allow any generalization from this. Apart from carbon in its various forms, some of the oxides and sulphides of the metallic elements, are the non-metallic conductors which have been most closely studied. Table VI. gives the resistance found in the case of copper and silver sulphide at various temperatures. It will be

TABLE VI.

Cu_2S		Ag_2S

192	13	..	..

seen that the increase in conductivity is extremely large for a comparatively small change of temperature, of the same order as the change in viscosity of many substances for an equivalent change. It seems likely that it is some such effect which accounts for the temperature coefficient.

Many of these substances exhibit a very remarkable property, in that the transition of electricity from one of them to a metallic conductor placed in contact, proceeds very much more easily in one direction than the other; in some cases the resistance is more than a thousand times greater in the one than the opposite sense. It is this property which is made use of in the rectifying devices used either for high frequency currents, as in the crystal detector, or for low frequency rectification on a small scale.

One other non-metallic conductor has been the subject of the most minute examination, namely selenium. In certain modifications this substance exhibits a very curious phenomenon; its resistance is changed by illumination. The conductivity in suitable circumstances may be increased by 6% by illumination of one metre candle, the effect within wide limits being proportional to the square root of the illumination.

Many attempts have been made to utilize this property for the measurement of light and for the production of electric currents corresponding to incident light for various purposes. Unfortunately the very large temperature coefficient, the variation of its resistance with humidity, and especially the slow response of selenium to weak illumination, usually stands in the way of complete successes. The effect is probably due to some allotropic modification produced in the material by light and it is not surprising that

NOTE: The resistances of the above depend to a great extent on the state of the surfaces, moisture, grease, etc., reducing the resistances enormously. The resistances are also greatly reduced for small increases in temperature. In actual practice, unless great care has been taken in keeping the surfaces clean, the effectual resistances of the substances may be $\frac{1}{10}$ or $\frac{1}{100}$ of the value shown in the table.

there should be a certain lag in its response to the stimulus if this view is correct.

Dielectric Conductors.—A large volume of unsystematic work for technical purposes has been carried out with what may be termed dielectric conductors or insulators. For most purposes the property required is the absence of conductivity, and therefore attention is centred mostly upon those substances which have the greatest possible resistance and can be made use of for

TABLE VIII.

insulating cables and the like. It is evident that such substances are not those likely to be chosen if it is desired to discover the mechanism of dielectric conduction. In general, as in the case of many of the non-metallic conductors, it is of dubious validity to employ the concept of electric resistance at all, as this is often in dielectrics, a function of the time as well as of the voltage applied. The resistance at room temperature for a few of the commoner insulators are given in the Table VII. In general the conductivity increases very rapidly with rising temperature, probably for the same reason that has been suggested in the case of non-metals. The accuracy of the measurements is vitiated in many cases by the presence of moisture which is apt to form in a thin conducting layer over parts of the surface. Thus in many cases, it is more important to use an insulator which can be thoroughly dried, than to seek one of a high specific resistance. At a sufficiently high voltage all these insulators break down and a spark occurs. This so-called dielectric strength is a matter of great technical importance, but it also depends to such a large extent upon the peculiar circumstances of the experiment, that only two typical cases, mica and crystal glass, are given as examples.

Some extremely valuable work, from a scientific point of view, has been carried out in the last few years by Pohl upon the transfer of electricity in certain dielectrics. He found that many dielectrics more especially sodium chloride exhibited a form of conductivity under the influence of light. This he could show was due to the production of photo-electric electrons whose displacements formed a current. Though this can scarcely be regarded as conductivity in the ordinary sense, it does represent one of the first cases in which the movement of electricity through a dielectric has been treated upon a quantitative basis.

(F. A. L.)

CONDUCTION IN LIQUIDS

In fused salts and conducting solutions the passage of an electric current is always accompanied by definite chemical changes; the substance of the conductor or electrolyte is decomposed, and the products of the decomposition appear at the electrodes. The chemical phenomena are considered in the article ELECTROLYSIS; we are here concerned solely with the mechanism of this *electrolytic* conduction of the current. In metallic conduction it is found that the current is proportional to the applied electromotive force—a relation known by the name of Ohm's law. According to this law $I=E/R$, where I is the current, E the electromotive force and R the resistance of the circuit. Ohm's law has been confirmed in the case of metallic conduction to a very high degree of accuracy and Kohlrausch was the first to show that an electrolyte possesses a definite resistance which has a constant value when measured with different currents and by different methods.

Measurement of the Resistance of Electrolytes.—There are two effects of the passage of an electric current which prevent the possibility of measuring electrolytic resistance by the ordinary methods with the direct currents which are used in the case of metals. The products of the chemical decomposition of the electrolyte appear at the electrodes and set up the opposing electromotive force of polarization, and unequal dilution of the solution may occur in the neighbourhood of the two electrodes. The polarization at the surface of the electrodes will set up an opposing electromotive force, and the unequal dilution of the solu-

tion will turn the electrolyte into a concentration cell and produce a subsidiary electromotive force either in the same direction as that applied or in the reverse according as the anode or the cathode solution becomes the more dilute. Both effects thus involve internal electromotive forces, and prevent the application of Ohm's law to the electrolytic cell as a whole. It is therefore necessary to eliminate both these effects before attempting to measure the resistance.

The usual and most satisfactory method of measuring the resistance of electrolytes is that of Kohlrausch and Holborn, which consists in eliminating the effects of polarization by the use of alternating currents, *i.e.*, currents that are reversed in direction many times a second. The chemical action produced by the first current is thus reversed by the second current in the opposite direction, and the polarization caused by the first current on the surface of the electrodes is destroyed before it rises to an appreciable value. The polarization is also diminished by increasing the area of the electrodes, which can be brought about to a very high degree by coating the plate with platinum black. The coating is effected by passing an electric current first one way and then the other between two platinum plates immersed in a 3% solution of platinum chloride to which a trace of lead acetate is sometimes added. The platinized plates thus obtained are quite satisfactory for the investigation of strong solutions. They have the power, however, of absorbing a certain amount of salt from the solutions and of giving it up again when water or more dilute solution is placed in contact with them. The measurement of very dilute solutions is thus made difficult, but if the plates be heated to redness after being platinized a grey surface is obtained which possesses sufficient area for use with dilute solutions and yet does not absorb an appreciable quantity of salt.

Any convenient source of alternating current may be used. The currents from the secondary circuit of a small induction coil from which the condenser has been removed are satisfactory for most purposes. With such currents it is necessary to consider the effects of self-induction in the circuit and of electrostatic capacity. In balancing the resistance of the electrolyte, resistance coils may be used in which self-induction and the capacity are reduced to a minimum by winding the wire of the coil backwards and forwards in alternate layers.

With these arrangements the usual method of measuring resistance by means of Wheatstone's bridge may be adapted to the case of electrolytes. With alternating currents, however, it is impossible to use a galvanometer in the usual way. The galvanometer was therefore replaced by Kohlrausch by a telephone, which gives a sound when an alternating current passes through it. The most common plan of the apparatus is shown diagrammatically in fig. (1). The electrolytic cell and a resistance box form two arms of the bridge, and the sliding contact is moved along the metre wire which forms the other two arms till no sound, or only a minimum sound, is heard in the telephone. The position of minimum sound is more sharply obtained by connecting a variable air condenser in parallel with the conductance cell so as to balance its capacity. The resistance of the electrolyte is to that of the box as that of the right-hand end of the wire is to that of the left-hand end. A more accurate method of using alternating currents dispenses with the telephone (*Phil. Trans.*, 1900, 194, p. 321). The current from one or two voltaic cells is led to an ebonite drum turned by a motor or a hand-wheel. On the drum are fixed brass strips with wire brushes touching them in such a manner that the current from the brushes is reversed several times in each revolution of the drum. The wires from the brushes are connected with the Wheatstone's bridge. A moving coil galvanometer is used as indicator, its connections being reversed in time with those of the battery by a slightly narrower set of brass strips fixed on the other end of the ebonite commutator. Thus any residual current through the galvanometer is direct and not alternating. The high moment of inertia of the

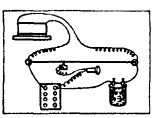

FIG. 1.—MEASUREMENT OF RESISTANCE BY WHEATSTONE'S BRIDGE AND TELEPHONE

coil makes the period of swing slow compared with the period of alternation of the current, and the slight periodic disturbances are thus prevented from affecting the galvanometer. When the measured resistance is not altered by increasing the speed of the commutator or changing the ratio of the arms of the bridge, the disturbing effects may be considered to be eliminated.

The form of vessel chosen to contain the electrolyte depends on the order of resistance to be measured. For dilute solutions the shape of cell shown in fig. (2) will be found convenient, while for more concentrated solutions, that indicated in fig. (3) is suitable. The absolute resistances of certain solutions have been determined by Kohlrausch by comparison with mercury, and, by using one of these solutions in any cell, the constant of that cell may be found once for all. From the observed resistance of any given solution in the cell the resistance of a centimetre cube —the so-called specific resistance—may be calculated. The reciprocal of this, or the conductivity, is a more generally useful constant; it is conveniently expressed in terms of a unit equal to the reciprocal of an ohm. Thus Kohlrausch found that a solution of potassium chloride, containing one-tenth of a gram equivalent (7·46 grams) per litre, has at 18° C a specific resistance of 89·37 ohms per cm. cube, or a conductivity of $1{\cdot}119\times10^{2}$ ohms or $1{\cdot}119\times10$ c.g.s. units. As temperature variation of conductivity is large, usually about 2% per degree, it is necessary to place the resistance cell in a paraffin or water bath, and to observe its temperature with some accuracy.

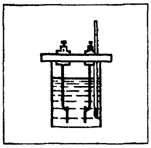

FIG. 2.—CELL FOR MEASUREMENT OF RESISTANCE OF DILUTE SOLUTIONS

An important objection to the use of the induction coil for accurate measurements is that it does not give a current of zero integral value, *i.e.*, the current is not alternating, but pulsating, having a uni-directional component. Another objection to this instrument is the difficulty of maintaining the frequency constant. A motor-driven small high frequency generator such as the Vreeland oscillator has been applied for conductance measurements. The most satisfactory source of alternating current for conductivity measurements is that provided by a thermionic value oscillator which gives a pure sine wave. The arrangement employed is illustrated in fig. (4). The frequency of the wave is varied by altering the capacity of the condenser C, which is of small capacity and continuously variable over its entire range and the condenser C' which is variable in steps of say 0·005 microfarad. Currents of from a few tenths to 25 amperes and having a frequency ranging from one-half to 5×10^{7} cycles may be obtained from this type of generator.

A principle employing direct current was adopted by E. Bouty in 1884 (*cf.* also Marie and W. A. Noyes *Journ. Amer. Chem. Soc.*, 1921). If a current be passed through two resistances in series by means of an applied electromotive force, the electric potential falls from one end of the resistances to the other, and, if Ohm's law be applied to each resistance in succession, it is seen that, since for each of them $E=IR$, and I the current is the same through both, E, the electromotive force or fall of potential between the ends of each resistance, must be proportional to the resistance between them. Thus by measuring the potential difference between the ends of the two resistances successively, their resistances may be compared. If, on the other hand, the potential differences are measured in some known units, and, similarly, the current flowing, the resistance of a single electrolyte can be determined.

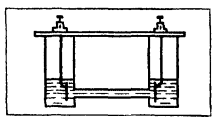

FIG. 3.—CELL FOR MEASUREMENT OF RESISTANCE OF CONCENTRATED SOLUTIONS

Equivalent Conductivity of Solutions.—The foundation of this knowledge was laid by Kohlrausch when he had developed the method of measuring electrolyte resistance described above. He expressed his results in terms of ***equivalent conductivity, i.e.***, the conductivity (κ) of the solution divided by the number (m)

of gram-equivalents of electrolyte per litre. He found that, as the concentration diminishes, the value of κ/m approaches a limit, and eventually becomes constant, that is to say, at great dilution the conductivity is proportional to the concentration. Kohlrausch first prepared very pure water by repeated distillation and found that its resistance continually increased as the process of purification proceeded. The conductivity of the water,

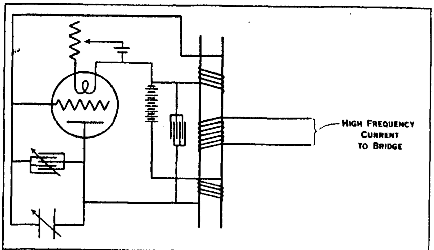

FIG. 4.—VALVE CIRCUIT FOR PROVIDING ALTERNATING CURRENT OF SINE-WAVE FORM

and of the slight impurities which must always remain, was subtracted from that of the solution made with it, and the result, divided by m, gave the equivalent conductivity of the substance dissolved. This procedure appears justifiable, for as long as conductivity is proportional to concentration it is evident that each part of the dissolved matter produces its own independent effect, so that the total conductivity is the sum of the conductivities of the parts; when this ceases to hold, the concentration of the solution has in general become so great that the conductivity of the solvent may be neglected. The general result of these experiments can be represented graphically by plotting κ/m as ordinates and $\sqrt[3]{m}$ as abscissae, $\sqrt[3]{m}$ being a number proportional to the reciprocal of the average distance between the molecules, to which it seems likely that the molecular conductivity may be related. The general types of curve for a simple neutral salt like potassium or sodium chloride and for a caustic alkali or acid are shown in fig. (5). The curve for the neutral salt reaches to a limiting value; that for the acid attains a maximum at a certain very small concentration, and falls again when the dilution is carried farther. The values of the molecular conductivities of all neutral salts are, at great dilution, of the same order of magnitude, while those of acids at their maxima are about three times as large. The influence of increasing concentration is greater with salts containing divalent ions, and greatest of all in solutions such as those of ammonia and acetic acid, which are substances of very low conductivity.

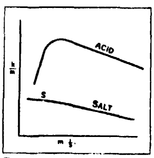

FIG. 5.—RELATION BETWEEN EQUIVALENT CONDUCTIVITY AND CONCENTRATION

Theory of Moving Ions.—The quantity of electricity flowing per second, *i.e.*, the current through the solution, depends on (1) the number of the ions concerned, (2) the charge on each ion, and (3) the velocity with which the ions travel past each other. Now, the number of ions is given by the concentration of the solution, for even if all the ions are not actively engaged in carrying the current at the same instant, they must, on any dynamical idea of chemical equilibrium, be all active in turn. The charge on each can be expressed in absolute units, and therefore the velocity with which they move past each other can be calculated. This was first done by Kohlrausch (*Göttingen Nachrichten*, 1876, and *Das Leitvermögen der Elektrolyte*, Leipzig, 1898). By combining the results of determinations of transport numbers by Hittorf's method with the sum of the velocities, as determined from the conductivities, Kohlrausch calculated the absolute velocities of different ions under stated conditions. The table shows Kohlrausch's values for the ionic velocities of three chlorides of alkali metals at 18° C, calculated for a potential gradient of 1 volt per cm. u is the velocity of the positive ion, v that of the negative ion; the numbers are in terms of a unit equal to 10^{-6} cm. per sec.:

	KCl			NaCl			LiCl		
m	$u+v$	u	v	$u+v$	u	v	$u+v$	u	v
0	1350	660	690	1140	450	690	1050	360	690
0·0001	1335	654	681	1129	448	681	1037	356	681
·001	1313	643	670	1110	440	670	1013	343	670
·01	1263	619	644	1059	415	644	962	318	644
·03	1218	597	621	1013	390	623	917	298	619
·1	1153	564	589	952	360	592	853	259	594
·3	1088	531	557	876	324	552	774	217	557
1·0	1011	491	520	765	278	487	651	169	482
3·0	911	442	469	582	206	376	463	115	348
5·0				438	153	285	334	80	254
10·0							117	25	92

These numbers show clearly that there is an increase in ionic velocity as the dilution proceeds. Moreover, if we compare the values for the chlorine ion obtained from observations on these three different salts, we see that as the concentrations diminish the velocity of the chlorine ion becomes the same in all of them. A similar relation appears in other cases, and, in general, it may be said that at great dilution the velocity of an ion is independent of the nature of the other ion present. This introduces the conception of specific ionic velocities, for which some values at 18° C are given by Kohlrausch in the following table:

K.	.	66×10^{-6} cms. per sec.	Cl.	.	69×10^{-6} cms. per sec.
Na	.	45 ,, ,, ,,	I.	.	69 ,, ,, ,,
Li	.	36 ,, ,, ,,	NO_3	.	64 ,, ,, ,,
NH_4	.	66 ,, ,, ,,	OH	.	162 ,, ,, ,,
H.	.	320 ,, ,, ,,	$C_2H_3O_2$		36 ,, ,, ,,
Ag	.	57 ,, ,, ,,	$C_3H_5O_2$		33 ,, ,, ,,

From these numbers can be deduced the conductivity of the dilute solution of any salt, and it was a comparison of the calculated with the observed values that furnished the first confirmation of Kohlrausch's theory. Some exceptions, however, are known. Thus acetic acid and ammonia give solutions of much lower conductivity than is indicated by the sum of the specific ionic velocities of their ions as determined from other compounds. An attempt to find in Kohlrausch's theory some explanation of this discrepancy shows that it could be due to one of two causes. Either the velocities of the ions must be much less in these solutions than in others, or else only a fractional part of the number of molecules present can be actively concerned in conveying the current. This point will again be considered later.

Friction on the Ions.—It is interesting to calculate the magnitude of the forces required to drive the ions with a certain velocity. A potential gradient of 1 volt per cm. leads to an electric force of 10^8 in c.g.s. units. The charge of electricity on 1 gram-equivalent of any ion is $1/\cdot0001036=9653$ units, hence the mechanical force acting on this mass is 9653×10^8 dynes. Suppose this produces a velocity u; then the force required to produce unit velocity is

$$P_o=\frac{9\cdot653\times10^{11}}{u}\text{ dynes}=\frac{9\cdot84\times10^5}{u}\text{ kg.-weight.}$$

If the ion have an equivalent weight A, then the force producing unit of velocity when acting on 1 gram is

$$P_1=9\cdot84\times\frac{10^5}{Au}\text{ kg.-weight.}$$

Thus, A being 39·1 and u being 660×10^{-6} for potassium, the aggregate force required to drive 1 gram of potassium ions with a velocity of 1 cm. per second through a very dilute solution must be equal to the weight of 38×10^6 kilograms.

Direct Measurement of Ionic Velocities.—Sir Oliver Lodge was the first to measure directly the velocity of an ion (*Brit. Ass. Report*, 1886). In a horizontal glass tube connecting two vessels filled with dilute sulphuric acid he placed a solution of sodium chloride in solid agar-agar jelly. This solid solution was made alkaline with a trace of caustic soda in order to bring out the red

colour of a little phenol-phthalein added as indicator. An electric current was then passed from one vessel to the other. The hydrogen ions from the anode vessel of acid were thus carried along the tube, and, as they travelled, decolourized the phenol-phthalein. By this method the velocity of the hydrogen ion through a jelly solution under a known potential gradient was observed to about 0·0026 cm. per sec., a number of the same order as that required by Kohlrausch's theory. Direct determinations of the velocities of a few other ions have been made by W. C. D. Whetham (*Phil. Trans.* vol. clxxxiv., A; vol. clxxxvi., A; *Phil. Mag.*, 1894). Two solutions having one ion in common, of equivalent concentrations, different densities, different colours, and nearly equal specific resistances, were placed one over the other in a vertical glass tube. In one case, for example, decinormal solutions of potassium carbonate and potassium bichromate were used. The colour of the latter is due to the presence of the bichromate group, Cr_2O_7. When a current was passed across the junction, the anions CO_3'' and Cr_2O travelled in the direction opposite to that of the current, and their velocity could be determined by measuring the rate at which the colour boundary moved. Similar experiments were made with alcoholic solutions of cobalt salts, in which the velocities of the ions were found to be much less than in water.

The behaviour of agar jelly was then investigated, and the velocity of an ion through a solid jelly was shown to be very little less than in an ordinary liquid solution. The velocities could therefore be measured by tracing the change in colour of an indicator or the formation of a precipitate. Thus decinormal jelly solutions of barium chloride and sodium chloride, the latter containing a trace of sodium sulphate, were placed in contact. Under the influence of an electromotive force the barium ions moved up the tube, disclosing their presence by the trace of insoluble barium sulphate formed. Again, a measurement of the velocity of the hydrogen, when travelling through the solution of an acetate, showed that its velocity was then only about the one-fortieth part of that found during its passage through chlorides. From this, as from the measurements on alcohol solutions, it is clear that where the equivalent conductivities are very low the effective velocities of the ions are reduced in the same proportion.

Another series of direct measurements has been made by Orme Masson (*Phil. Trans.*, vol. cxcii., A). He placed the gelatine solution of a salt, potassium chloride, for example, in a horizontal glass tube, and found the rate of migration of the potassium and chlorine ions by observing the speed at which they were replaced when a coloured anion, say, the Cr_2O_7 from a solution of potassium bichromate, entered the tube at one end, and a coloured cation, say, the Cu from copper sulphate, at the other. The coloured ions are specifically slower than the colourless ions which they follow, and in this case it follows that the coloured solution has a higher resistance than the colourless. For the same current, therefore, the potential gradient is higher in the coloured solution and lower in the colourless one. Thus a coloured ion which passes in front of the advancing boundary finds itself acted on by a smaller force and falls back into line, while a straggling colourless ion is pushed forward again. Hence a sharp boundary is preserved. B. D. Steele has shown that with these sharp boundaries the use of coloured ions is unnecessary, the junction line being visible owing to the difference in the optical refractive indices of two colourless solutions. Once the boundary is formed, too, no gelatine is necessary, and the motion can be watched through liquid aqueous solutions. (*See* R. B. Denison and B. D. Steele, *Phil. Trans.*, 1906.)

All the direct measurements which have been made on simple binary electrolytes agree with Kohlrausch's results within the limits of experimental error. His theory, therefore, probably holds good in such cases, whatever be the solvent, if the proper values are given to the ionic velocities, *i.e.*, the values expressing the velocities with which the ions actually move in the solution of the strength taken, and under the conditions of the experiment. If the specific velocity of any one ion is known, it is possible to deduce, from the conductivity of very dilute solutions, the velocity of any other ion with which it may be associated, a proceeding which does not involve the difficult task of determining the migration constant of the compound. Thus, taking the specific ionic velocity of hydrogen as 0·00032 cm. per sec., by determining the conductivity of dilute solutions of any acid, the specific velocity of the acid radicle involved can be found. Or again, since the specific velocity of silver is known, the velocities of a series of acid radicles at great dilution can be found by measuring the conductivity of their silver salts.

By such methods W. Ostwald, G. Bredig and other observers have found the specific velocities of many ions both of inorganic and organic compounds, and examined the relation between constitution and ionic velocity. The velocity of elementary ions is found to be a periodic function of the atomic weight, similar elements lying on corresponding portions of a curve drawn to express the relation between these two properties. Such a curve much resembles that giving the relation between atomic weight and viscosity in solution. For complex ions the velocity is largely an additive property; to a continuous additive change in the composition of the ion corresponds a continuous but decreasing change in the velocity. The following table gives Ostwald's results for the formic acid series:—

		Velocity	Difference for CH_2
Formic acid	HCO_2	51·2	. .
Acetic "	$H_3C_2O_2$	38·3	−12·9
Propionic "	$H_5C_3O_2$	34·3	− 4·0
Butyric "	$H_7C_4O_2$	30·8	− 3·5
Valeric "	$H_9C_5O_2$	28·8	− 2·0
Caprionic "	$H_{11}C_6O_2$	27·4	− 1·4

The Theory of Debye and Hückel.—In the investigations of Debye and Hückel a theory has been developed which though not complete may be considered to have furnished already for dilute solutions of strong electrolytes a complete explanation of the main properties (*Phys. Zeits.* 1924; *Trans. Faraday Soc.*, 1927; *see* also ELECTROLYSIS for the bearing of this theory on the activity of an electrolyte). In this theory, which assumes complete dissociation of strong electrolytes, the view has been developed that the fall of molecular conductivity observed with increasing concentration is due not to a diminution of the number of ions but to a reduction of their mobility on account of electrostatic forces. The electrostatic potential at the surface of the ion induces an ionic atmosphere of opposite charge, the density of which decreases with increasing distance from the centre of the ion. In the equilibrium condition the ionic atmosphere will possess central symmetry, but on subjecting an electrolyte to an external field so as to generate a current and a mean movement of each ion in one direction the central symmetry of the ionic system will be destroyed. If, for instance, the central ion moves to the right, then during its motion it will constantly have to build up a charge density constituting its atmosphere to the right, whereas to the left the charge density will have to die out. If the creation of the ionic atmosphere could be accomplished instantaneously, no effect of the motion would be perceptible. If, however, a finite time of relaxation exists, during the motion of the central ion the atmosphere will, in the right-hand part, never reach its equilibrium density, whereas in the left-hand part the density will constantly be larger than its equilibrium value. Since the charge density in the atmosphere always has a sign opposite to the charge of the ion, it follows that, owing to the dissymmetry of its atmosphere, the central ion will be acted upon by a force tending to decrease its velocity. As the amount of dissymmetry increases with increasing velocity, this force will also increase, so that it will have the same effect that an increase of the friction constant would have. It is shown by Debye and Hückel that the decrease of density of the ionic atmosphere with distance is given by the exponential $\epsilon^{-\chi r}$ where r is the distance and χ has the dimensions of a reciprocal length denoting the distance at which the charge density has fallen to $1/\epsilon$ of its initial value.

It can be shown (*cf.* ELECTROLYSIS) that χ is given by the equation

$$\chi^2 = \frac{4\pi}{DkT}\sum n_i \epsilon_i^2$$

when D = dielectric constant of the solvent, $k = 1{\cdot}37 \times 10^{-16}$ = Boltzmann's constant, T = absolute temperature, n_i = number of ions of kind i in 1 c.c., ϵ_i = charge of one ion of kind i. For a univalent electrolyte of concentration m calculated in mols. per litre and in the solvent water, it is found

$$\chi = 3{\cdot}27 \times 10^{7}\sqrt{m} \quad \text{or} \quad 1/\chi = 3{\cdot}06 \times 10^{-8}/\sqrt{m} \text{ cm.}$$

$1/\chi$ is called the radius of the ionic atmosphere. The conductivity λ of any electrolyte solution may be stated in a most general way to be given by the expression $\lambda = \sum \frac{n_i \epsilon_i^2}{\rho_i}$ where ρ_i is the friction coefficient of an ion of kind i. The frictional force in the medium which has to be overcome during the steady motion is accordingly given by the product $\rho_i v_i$, where v_i is the mean velocity of the ion.

The present theory is built up on the assumption of total dissociation, according to which n_i is exactly proportional to the total concentration, and the deviations of the proportionality between the conductivity and the concentration are accordingly due to changes with concentration of the friction coefficients ρ_i or their reciprocals, the mobilities.

According to the reasoning followed above, a change of mobility with concentration is to be expected, provided a time of relaxation characteristic of the ionic atmosphere exists. An expression is developed for the space distribution of ions, allowing for its variation in time by supposing a total central charge E in equilibrium with its ionic atmosphere to be destroyed at the instant $t=0$ and determining how the charge density of the atmosphere spreads out to zero density. A mathematical expression is thus derived for the charge density, or the potential, as a function of the distance from the centre r and the time t. An essential time constant τ governing the decrease and known as the time of relaxation is derived. In the case of an electrolyte with two univalent ions of equal mobility (like KCl) τ is given by the expression

$$\tau = \frac{\rho}{\chi^2 kT}.$$

For a KCl solution of m mols per litre, this gives

$$\tau = \frac{0{\cdot}55}{m} 10^{-10} \text{ sec.}$$

When an ion moves with a given constant velocity in the direction of the external field, the additional field intensity F_1, in the direction opposite to the motion of the central ion is given by the expression

$$F_1 = \frac{1}{6} \frac{E}{D} \frac{\chi\rho}{kT} v.$$

where E is the total charge of the central ion and ρ is the mean friction coefficient of the solution.

For a solution in which the ions have equal mobilities the additional force or product of the ionic charge and the additional field intensity is given by the expression

$$EF_1 = -\frac{R_0 E^2 \chi}{6DkT}$$

where $R_0 = \rho v$ is the frictional force on a central ion in an infinitely dilute solution. For a KCl solution in water of concentration m mols. per litre, this additional force has the absolute value $0{\cdot}384\sqrt{m}$ showing that the effect is of practical importance. In an infinitely dilute solution, P may be used to represent the frictional constant so that in this case $R_0 = Pv$.

In Stokes formula, the frictional force is given by the expression $R_0 = 6\pi\eta Cv$ where C is the radius of the moving sphere and η the internal friction constant of the liquid. In this formula it is supposed that no external force acts on the liquid surrounding the sphere. In the present case however the external field will also act on the charges constituting the atmosphere in accordance with the principle of electrophoresis, the relations of which have been calculated by Helmholtz. The charges in the liquid and the charge of the sphere always have opposite sign. The additional motion due to the existence of these charges will therefore have a velocity oppositely directed to the velocity of the particle. It follows that, in addition to the Stokes force, an additional force

$$R_1 = EF_0 C\chi$$

will act in a direction opposite to the direction of motion. For a uni-univalent solution in water, by substituting the value for χ it is seen that the additional force will be represented by the expression

$$R_1 = EF_0 C\sqrt{m} \times 0{\cdot}327 \times 10^{8},$$

showing that for particles of the size of ions (*i.e.*, values of C of the order of 10^{-8} cm.) this additional force will also be of practical importance.

Combining all the foregoing results and calculating the migration velocity of the central ion from the condition that the whole electric force $E(F_0+F_1)$ has to be equal to the whole frictional force R_0+R_1, we have

$$EF_0 - \frac{E^2}{6D}\frac{\rho\chi}{kT} v = \rho v + EC\chi F_0.$$

Hence it follows that the migration velocity of an ion with charge E and the frictional constant P should be represented by the formula

$$v = \frac{EF_0}{P} \frac{1 - C\chi}{1 + \frac{\rho}{P}\frac{E^2\chi}{6DkT}} = \frac{EF_0}{P}\left[1 - C\chi - \frac{\rho}{P}\frac{E^2\chi}{6DkT}\right].$$

According to this formula the correction of the migration velocity in infinite dilution is proportional to χ (the reciprocal of the radius of the ionic layer) and therefore proportional to the square root of the concentration.

In the case of a uni-univalent electrolyte, calling Λ_0 the limiting value of the molar conductivity at infinite dilution and Λ the molar conductivity at a certain small concentration, the theory leads from the above expressions for the migration velocity to the formula

$$\frac{\Lambda_0 - \Lambda}{\Lambda_0} = \left[\frac{C_1\rho_2 + C_2\rho_1}{\rho_1+\rho_2} + \frac{\rho_1^2+\rho_2^2}{2\rho_1\rho_2}\frac{\epsilon^2}{6DkT}\right]\chi$$

where ρ_1 and ρ_2 are frictional coefficients for anion and cation respectively. Substituting numerical values for solutions in water at 18°C. we have

$$\frac{\Lambda_0 - \Lambda}{\Lambda_0} = \left[0{\cdot}233 \times 10^{8}\frac{C_1\rho_2 + C_2\rho_1}{\rho_2+\rho_1} + 0{\cdot}273\frac{\rho_1^2+\rho_2^2}{2\rho_1\rho_2}\right]\sqrt{2m}.$$

It is possible to avoid the introduction of the ionic radii C_1 and C_2 by taking in accordance with Stokes formula,

$$\rho_1 = 6\pi\eta C_1, \quad \rho_2 = 6\pi\eta C_2$$

and taking η as the ordinary viscosity of the liquid. Performing this elimination gives the formula

$$\frac{\Lambda_0 - \Lambda}{\Lambda_0} = \left[\frac{1}{3\pi\eta}\frac{N\epsilon^2}{\Lambda_0} + \frac{\rho_1^2+\rho_2^2}{2\rho_1\rho_2}\frac{\epsilon^2}{6DkT}\right]\chi$$

in which $N = 6{\cdot}06 \times 10^{23}$ = Avagadro's number, or substituting numerical values,

$$\frac{\Lambda_0 - \Lambda}{\Lambda_0} = \left[\frac{35{\cdot}6}{\Lambda_0} + 0{\cdot}273\frac{\rho_1^2+\rho_2^2}{2\rho_1\rho_2}\right]\sqrt{2m}.$$

This expression can also be written in the following form which is applicable to all solvents

$$\frac{\Lambda_0 - \Lambda_c}{\Lambda_0} = \left(\frac{K_1}{D^{\frac{3}{2}}}\omega_1 + \frac{K_2}{D^{\frac{1}{2}}} b\right)\sqrt{2m},$$

where $\omega_1 = \frac{1}{2}\left(\frac{l_a}{l_c} + \frac{l_c}{l_a}\right)$, and K_1 and K_2 are universal constants varying only with the temperature l_c and l_a the mobilities of the cation and anion b the harmonic mean of the ionic radii and c the molecular concentration.

It is pointed out by Onsager (*Trans. Faraday Soc.* 1927) that on account of the Brownian movements of the central ion the

value of the additional force due to the dissymmetry of the ionic atmosphere has to be corrected. If the mobilities of the two ions are equal, his correction factor has the value $2-\sqrt{2}=0\cdot586$. Introducing this correction the theoretical expression in the case of KCl ($\rho_1=\rho_2$) becomes

$$\frac{\Lambda_0-\Lambda}{\Lambda_0}=\left[\frac{35\cdot6}{\Lambda_0}+0\cdot160\right]\sqrt{2m}$$

which gives for $\Lambda_0=129\cdot9$ the value of 0·433 for the factor which is close to its experimental value 0·461. It has been shown that these equations are in good agreement with the best conductivity data for aqueous solutions; and data compiled by H. Hartley and R. P. Bell (*Trans. Faraday Soc.*, 1927) of conductivity measurements in a large number of solvents show a general agreement in many cases with the above expressions. In other instances, however, deviations occur which appear to be due to the formation of complexes or else to lack of complete ionization of the electrolyte. In general the evidence obtained thus so far agrees so well with the theory that it seems reasonable to accept the assumption that typical strong electrolytes (salts) are practically completely dissociated at all concentrations, at least in solvents of high dielectric constant, though this theory of complete dissociation fails to cover the behaviour of those weak electrolytes which obey Ostwald's dilution law (*see* ELECTROLYSIS) just as completely as this latter law fails to cover the behaviour of highly dissociated metallic salts.

CONDUCTION OF, IN GASES

A gas such as air when it is under normal conditions conducts electricity to a small but only to a very small extent, however small the electric force acting on the gas may be. The electrical conductivity of gases not exposed to special conditions is so small that it was only definitely established in the early years of the 20th century, although it had engaged the attention of physicists for more than a hundred years. It had been known for a long time that a body charged with electricity slowly lost its charge even when insulated with the greatest care, and though long ago some physicists believed that part of the leak of electricity took place through the air, the general view seems to have been that it was due to almost unavoidable defects in the insulation or to dust in the air, which after striking the charged body was repelled from it and went off with some of the charge. C. A. Coulomb, who made some very careful experiments which were published in 1785 (*Mém. de l'Acad. des Sciences*, 1785, p. 612), came to the conclusion that after allowing for the leakage along the threads which supported the charged body there was a balance over, which he attributed to leakage through the air. His view was that when the molecules of air come into contact with a charged body some of the electricity goes on to the molecules, which are then repelled from the body carrying their charge with them. We shall see later that this explanation is not tenable. C. Matteucci (*Ann. chim. phys.*, 1850, 28, p. 390) in 1850 also came to the conclusion that the electricity from a charged body passes through the air; he was the first to prove that the rate at which electricity escapes is less when the pressure of the gas is low than when it is high. He found that the rate was the same whether the charged body was surrounded by air, carbonic acid or hydrogen. Subsequent investigations have shown that the rate in hydrogen is in general much less than in air. Thus in 1872 E. G. Warburg (*Pogg. Ann.*, 1872, 145, p. 578) found that the leak through hydrogen was only about one-half of that through air: he confirmed Matteucci's observations on the effect of pressure on the rate of leak, and also found that it was the same whether the gas was dry or damp. He was inclined to attribute the leak to dust in the air, a view which was strengthened by an experiment of J. W. Hittorf's (*Wied. Ann.*, 1879, 7, p. 595), in which a small carefully insulated electroscope, placed in a small vessel filled with carefully filtered gas, retained its charge for several days; we know now that this was due to the smallness of the vessel and not to the absence of dust, as it has been proved that the rate of leak in small vessels is less than in large ones.

Great light was thrown on this subject by some experiments on the rates of leak from charged bodies in closed vessels made almost simultaneously by H. Geitel (*Phys. Zeit.*, 1900, 2, p. 116) and C. T. R. Wilson (*Proc. Camb. Phil. Soc.*, 1900, 11, p. 32). These observers established that (1) the rate of escape of electricity in a closed vessel is much smaller than in the open, and the larger the vessel the greater is the rate of leak; and (2) the rate of leak does not increase in proportion to the differences of potential between the charged body and the walls of the vessel: the rate soon reaches a limit beyond which it does not increase, however much the potential difference may be increased, provided, of course, that this is not great enough to cause sparks to pass from the charged body. On the assumption that the maximum leak is proportional to the volume, Wilson's experiments, which were made in vessels less than 1 litre in volume, showed that in dust-free air at atmospheric pressure the maximum quantity of electricity which can escape in one second from a charged body in a closed volume of V cubic centimetres is about $10^{-8}V$ electrostatic units.

E. Rutherford and S. T. Allan (*Phys. Zeit.*, 1902, 3, p. 225), working in Montreal, obtained results in close agreement with this. Working between pressures of from 43 to 743 millimetres of mercury, Wilson showed that the maximum rate of leak is very approximately proportional to the pressure; it is thus exceedingly small when the pressure is low—a result illustrated in a striking way by an experiment of Sir W. Crookes (*Proc. Roy. Soc.*, 1879, 28, p. 347) in which a pair of gold leaves retained an electric charge for several months in a very high vacuum. Subsequent experiments have shown that it is only in very small vessels that the rate of leak is proportional to the volume and to the pressure; in large vessels the rate of leak per unit volume is considerably smaller than in small ones. In small vessels the maximum rate of leak in different gases, is, with the exception of hydrogen, approximately proportional to the density of the gas. Wilson's results on this point are shown in the following table (*Proc. Roy. Soc.*, 1901, 60, p. 277):—

Gas	Relative rate of leak	*Rate of leak* / Sp.Gr.
Air	1·00	1
H_2	·184	2·7
CO_2	1·69	1·10
SO_2	2·64	1·21
CH_3Cl	4·7	1·09
$Ni(CO)_4$	5·1	·867

The rate of leak of electricity through gas contained in a closed vessel depends to some extent on the material of which the walls of the vessel are made; thus it is greater, other circumstances being the same, when the vessel is made of lead than when it is made of aluminium. It also varies, as Campbell and Wood (*Phil. Mag.* [6], 13, p. 265) have shown, with the time of the day, having a well-marked minimum at about 3 o'clock in the morning: it also varies from month to month. Rutherford (*Phys. Rev.*, 1903, 16, p. 183), Cooke (*Phil. Mag.*, 1903 [6], 6, p. 403) and M'Clennan and Burton (*Phys. Rev.*, 1903, 16, p. 184) have shown that the leak in a closed vessel can be reduced by about 30% by surrounding the vessel with sheets of thick lead, but that the reduction is not increased beyond this amount, however thick the lead sheets may be. This result indicates that part of the leak is due to a very penetrating kind of radiation, which can get through the thin walls of the vessel but is stopped by the thick lead. A large part of the leak we are describing is due to the presence of radioactive substances such as radium and thorium in the earth's crust and in the walls of the vessel, and to the gaseous radioactive emanations which diffuse from them into the atmosphere. This explains the very interesting effect discovered by J. Elster and H. Geitel (*Phys. Zeit.*, 1901, 2, p. 560), that the rate of leak in caves and cellars when the air is stagnant and only renewed slowly is much greater than in the open air.

In some cases the difference is very marked; thus they found that in the cave called the Baumannshöhle in the Harz mountains the electricity escaped at seven times the rate it did in the air outside. In caves and cellars the radioactive emanations from the walls can accumulate and are not blown away as in the open air.

The conductivity of normal air arises from several causes; part of it may be due to the presence of radioactive substances in the walls of the vessel in which the gas is contained, or to a little radioactive emanation in the gas itself. The conductivity is so small that a mere trace of radioactive substances or of radioactive properties in ordinary matter would be sufficient to account for it. The metal of the containing vessel has certainly a considerable effect on the conductivity of the gas inside; this may, however, be due not to an intrinsic radiation of the metal but to a radiation excited by the passage through the metal of a very penetrating radiation for the existence of which there is strong evidence. That the intrinsic radioactivity of the metal and gas cannot be the sole cause of the conductivity is shown by experiments like that made by M'Clennan (*Phil. Mag.*, v. 24, p. 520, 1912), who measured the conductivity in a hermetically sealed vessel in Canada, England and Scotland and on board a steamship in the Atlantic; he found that the conductivity was much the same at the different land stations, and could be represented by the production of about 9 ions per c.c. of the gas per sec., but that the conductivity over the sea was considerably less, and was equivalent to only 6 ions per c.c. per sec. This indicates that some of the conductivity of the gas is due to radiation coming from the land, and that this radiation is cut off by the ocean. This is confirmed by the fact discovered by M'Clennan and M'Collum (*Phil. Mag.*, vi. 22, p. 629, 1911), Wulf (*Phys. Tech.* xi. p. 811) and Bergwitz (*Hahlibakonschrift,* Brunswick, 1910) that at the top of high towers the conductivity is less than on the ground; this is what we should expect since the radiation is absorbed by the atmosphere. Observations on the conductivity of the air in vessels taken up in balloons by Gockel (*Phys. Zeit.*, x. p. 845, 1909; xii. p. 595, 1911), Hess (*Phys. Zeit.*, xii. p. 998, 1911), and especially by Kolhörster (*Phys. Zeit.*, xiv. pp. 1066, 1153, 1913, *Deutsch. Phys. Gesell. Verh.*, xvi. 14, p. 719, 1914) have brought to light the very interesting fact that the diminution in the conductivity with height ceases when the height exceeds some two kilometres and at greater altitudes is succeeded by an *increase* in conductivity with altitude.

Kolhörster found that at the height of nine kilometres the conductivity in a sealed vessel was some ten times that at the surface of the earth. These variations of the conductivity with the height are what would occur if the conductivity were produced by radiations of two different types (1) a radiation coming from the ground and (2) another coming from the sky. The effects due to (1) would diminish as the height increased while that due to (2) would increase. Estimates of the amount of conductivity due to (2) at the surface of the earth have been made by various observers, and it would seem that it may be represented by the production of about 1·5 ions per c.c. per sec.; as the conductivity at sea-level generally requires the production of from 10–20 ions per c.c. per sec.; much the greater part of the conductivity at the earth's surface must be due to radiation of type 1. Millikan and Bowen give the following results for the conductivity due to radiation of type 2 at different altitudes, the numbers being the number of ions produced per c.c. per sec.: 1·4 at sea-level, 2·6 at 1,600 metres, 4·8 at 1,600 metres, 5·9 at 4,300 metres. Kolhörster (Berlin, *Berichte*, 1923, p. 366) by making observations at the surface, and in caverns of glaciers on the Jungfrau, measured the absorption of these rays by ice, and found an absorption coefficient of about 2·5 per metre; this is much smaller than that of the γ radiation from any known radioactive substance. He found a diurnal variation in the amount of the radiation and suggested that it might be connected with the Milky Way.

Many observations on this radiation have been made by Millikan and his collaborators (*Nature*, Jan. 7, 1928), who have measured the conductivity in vessels submerged at different depths in two mountain lakes on Mount Whitney. Lake Muir, at an altitude of 11,800 ft., and Arrowhead lake at an altitude of 5,100. These lakes are fed by melted snow so that the water is not likely to contain radioactive matter. It appears from these measurements that the radiation is by no means homogeneous, as the absorption coefficient was greater at the surface of the lake than at the greatest depth at which observations were taken. No trace of the diurnal effect observed by Kolhörster was detected. It was found, too, from observations made in the southern hemisphere on the Andes in Bolivia, that both the character and the amount of the radiation was much the same in the two hemispheres, indicating that the radiation comes pretty uniformly from all parts of the heavens. Applying an expression due to Compton for the connection between the absorption and wave-length it was found that the wave length of the most penetrating radiation was ·00038 Å; the quantum of energy corresponding to this wave-length is about 32 million volts. This is much greater than the energy associated with any known γ radiation. Many suggestions have been made as to its origin. Jeans and Eddington have suggested that it arises from the coalescence of an electron with a positive particle and the conversion of their energy and mass into those of radiation; this would give a radiation more penetrating than that found though it might be degraded by passing through matter. C. T. R. Wilson has suggested the possibility of the radiation being excited by electrons which have acquired energy amounting to millions of volts under the action of something analogous to thunderstorms. This is in accordance with the laws which govern the passage of electrons through gases but Millikan finds no difference in the amount of radiation in regions where thunderstorms are frequent and in those where they are rare. We do not know enough at present about these rays to decide either as to their nature or the place of their origin; it is evident, however, that they raise questions of the greatest interest and importance.

The electrical conductivity of gases in the normal state is, as we have seen, exceedingly small, so small that the investigation of its properties is a matter of considerable difficulty; there are, however, many ways by which the electrical conductivity of a gas can be increased so greatly that the investigation becomes comparatively easy. Gases drawn from the neighbourhood of flames, electric arcs and sparks, or glowing pieces of metal or carbon are conductors, as are also gases through which Röntgen or cathode rays or rays of positive electricity are passing; the rays from the radioactive metals, radium, thorium, polonium and actinium, produce the same effect, as does also ultra-violet light of exceedingly short wave-length. The gas, after being made a conductor of electricity by any of these means, is found to possess certain properties; thus it retains its conductivity for some little time after the agent which made it a conductor has ceased to act; the conductivity, however, diminishes very rapidly and finally gets too small to be appreciable.

This and several other properties of conducting gas may readily be proved by the aid of the apparatus represented in fig. 1. V is a testing vessel in which an electroscope is placed. Two tubes A and C are fitted into the vessel, A being connected with a water pump, while the far end of C is in the region where the gas is exposed to the agent, which makes it a conductor of electricity. Let us suppose that the gas is made conducting by Röntgen rays produced by a vacuum tube which is placed in a box, covered except for a window at B with lead so as to protect the electroscope from the direct action of the rays. If a slow current of air is drawn by the water pump through the testing vessel, the charge on the electroscope will gradually leak away. The leak, however, ceases when the current of air is stopped. This result shows that the gas retains its conductivity during the time taken by it to pass from one end to the other of the tube C.

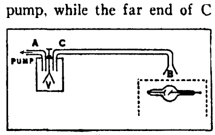

FIG. 1

The gas loses its conductivity when filtered through a plug of glass-wool, or when it is made to bubble through water. This can readily be proved by inserting in the tube C a plug of glass-wool or a water trap; then if by working the pump a little harder

the same current of air is produced as before, it will be found that the electroscope will now retain its charge, showing that the conductivity can, as it were, be filtered out of the gas. The conductivity can also be removed from the gas by making the gas traverse a strong electric field. We can show this by replacing the tube C by a metal tube with an insulated wire passing down the axis of the tube. If there is no potential difference between the wire and the tube then the electroscope will leak when a current of air is drawn through the vessel, but the leak will stop if a considerable difference of potential is maintained between the wire and the tube: this shows that a strong electric field removes the conductivity from the gas.

The fact that the conductivity of the gas is removed by filtering shows that it is due to something mixed with the gas which is removed from it by filtration, and since the conductivity is also removed by an electric field, the cause of the conductivity must be charged with electricity so as to be driven to the sides of the tube by the electric force. Since the gas as a whole is not electrified either positively or negatively, there must be both negative and positive charges in the gas, the amount of electricity of one sign being equal to that of the other. We are thus led to the conclusion that the conductivity of the gas is due to electrified particles being mixed up with the gas, some of these particles having charges of positive electricity, others of negative. These electrified particles are called *ions*, and the process by which the gas is made a conductor is called the ionization of the gas. We shall show later that the charges and masses of the ions can be determined, and that the gaseous ions are not identical with those met with in the electrolysis of solutions.

One very characteristic property of conduction of electricity through a gas is the relation between the current through the gas and the electric force which gave rise to it. This relation is not in general that expressed by Ohm's law, which always, as far as our present knowledge extends, expresses the relation for conduction through metals and electrolytes. With gases, on the other hand, it is only when the current is very small that Ohm's law is true. If we represent graphically by means of a curve the relation between the current passing between two parallel metal plates separated by ionized gas and the difference of potential between the plates, the curve is of the character shown in fig. 2, when the ordinates represent the current and the abscissae the difference of potential between the plates. We see that when the potential difference is very small, *i.e.*, close to the origin, the curve is approximately straight, but that soon the current increases much less rapidly than the potential difference, and that a stage is reached when no appreciable increase of current is produced when the potential difference is increased; when this stage is reached the current is constant, and this value of the current is called the "saturation" value. When the potential difference approaches the value at which sparks would pass through the gas, the current again increases with the potential difference; thus the curve representing the relation between the current and potential difference over very wide ranges of potential difference has the shape shown in fig. 3; curves of this kind have been obtained by von Schweidler (*Wien. Ber.*, 1899, 108, p. 273), and J. E. S. Townsend (*Phil. Mag.*, 1901 [6], 1, p. 198). We shall discuss later the causes of the rise in the current with large potential differences, when we consider ionization by collision.

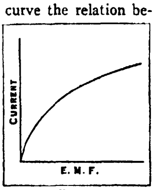

FIG. 2

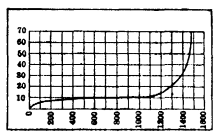

FIG. 3

The general features of the earlier part of the curve are readily explained on the ionization hypothesis. On this view the Röntgen rays or other ionizing agent acting on the gas between the plates, produces positive and negative ions at a definite rate. Let us suppose that q positive and q negative ions are by this means produced per second between the plates; these under the electric force will tend to move, the positive ones to the negative plate, the negative ones to the positive. Some of these ions will reach the plate, others before reaching the plate will get so near one of the opposite sign that the attraction between them will cause them to unite and form an electrically neutral system; when they do this they end their existence as ions. The current between the plates is proportional to the number of ions which reach the plates per second. Now it is evident that we cannot go on taking more ions out of the gas than are produced; thus we cannot, when the current is steady, have more than q positive ions driven to the negative plate per second, and the same number of negative ions to the positive. If each of the positive ions carries a charge of e units of positive electricity, and if there is an equal and opposite charge on each negative ion, then the maximum amount of electricity which can be given to the plates per second is qe, and this is equal to the saturation current. Thus if we measure the saturation current, we get a direct measure of the ionization, and this does not require us to know the value of any quantity except the constant charge on the ion. If we attempted to deduce the amount of ionization by measurements of the current before it was saturated, we should require to know in addition the velocity with which the ions move under a given electric force, the time that elapses between the liberation of an ion and its combination with one of the opposite sign, and the potential difference between the plates. Thus if we wish to measure the amount of ionization in a gas we should be careful to see that the current is saturated.

The difference between conduction through gases and through metals is shown in a striking way when we use potential differences large enough to produce the saturation current. Suppose we have got a potential difference between the plates more than sufficient to produce the saturation current, and let us increase the distance between the plates. If the gas were to act like a metallic conductor this would diminish the current, because the greater length would involve a greater resistance in the circuit. In the case we are considering the separation of the plates will *increase* the current, because now there is a larger volume of gas exposed to the rays; there are therefore more ions produced, and as the saturation current is proportional to the number of ions the saturation current is increased. If the potential difference between the plates were much less than that required to saturate the current, then increasing the distance would diminish the current; the gas for such potential differences obeys Ohm's law and the behaviour of the gaseous resistance is therefore similar to that of a metallic one.

In order to produce the saturation current the electric field must be strong enough to drive each ion to the electrode before it has time to enter into combination with one of the opposite sign. Thus when the plates in the preceding example are far apart, it will take a larger potential difference to produce this current than when the plates are close together. The potential difference required to saturate the current will increase as the square of the distance between the plates, for if the ions are to be delivered in a given time to the plates their speed must be proportional to the distance between the plates. But the speed is proportional to the electric force acting on the ion; hence the electric force must be proportional to the distance between the plates, and as in a uniform field the potential difference is equal to the electric force multiplied by the distance between the plates, the potential difference will vary as the square of this distance.

The potential difference required to produce saturation will, other circumstances being the same, increase with the amount of ionization, for when the number of ions is large and they are crowded together, the time which will elapse before a positive one combines with a negative will be smaller than when the number of ions is small. The ions have therefore to be removed more quickly from the gas when the ionization is great than when it is small; thus they must move at a higher speed and must therefore be acted upon by a larger force.

When the ions are not removed from the gas, they will increase until the number of ions of one sign which combine with ions of

the opposite sign in any time is equal to the number produced by the ionizing agent in that time. We can easily calculate the number of free ions at any time after the ionizing agent has commenced to act.

Coefficient of Recombination.—Let q be the number of ions (positive or negative) produced in one cubic centimetre of the gas per second by the ionizing agent, n_1, n_2, the number of free positive and negative ions respectively per cubic centimetre of the gas. The number of collisions between positive and negative ions per second in one cubic centimetre of the gas is proportional to n_1n_2. If a certain fraction of the collisions between the positive and negative ions result in the formation of an electrically neutral system, the number of ions which disappear per second in a cubic centimetre will be equal to $\alpha n_1, n_2$, where α is a quantity which is independent of n_1, n_2; hence if t is the time since the ionizing agent was applied to the gas, we have

$$dn_1/dt = q - \alpha n_1 n_2,\ dn_2/dt = q - \alpha n_1 n_2.$$

Thus $n_1 - n_2$ is constant, so if the gas is uncharged to begin with, n_1 will always equal n_2. Putting $n_1 = n_2 = n$ we have

$$dn/dt = q - \alpha n^2 \qquad (1),$$

the solution of which is, since $n = 0$ when $t = 0$,

$$n = \frac{k(\epsilon^{2k\alpha t} - 1)}{\epsilon^{2k\alpha t} + 1} \qquad (2),$$

if $k^2 = q/\alpha$. Now the number of ions when the gas has reached a steady state is got by putting t equal to infinity in the preceding equation, and is therefore given by the equation

$$n_0 = k = \sqrt{(q/\alpha)}.$$

We see from equation (2) that the gas will not approximate to its steady state until $2k\alpha t$ is large, that is until t is large compared with $1/2k\alpha$ or with $1/2\sqrt{(q\alpha)}$. We may thus take $1/2\sqrt{(q\alpha)}$ as a measure of the time taken by the gas to reach a steady state when exposed to an ionizing agent; as this time varies inversely as $\sqrt{q}$ we see that when the ionization is feeble it may take a very considerable time for the gas to reach a steady state. Thus in the case of our atmosphere where the production of ions is only at the rate of about 30 per cubic centimetre per second, and where, as we shall see, α is about 10^{-6}, it would take some minutes for the ionization in the air to get into a steady state if the ionizing agent were suddenly applied.

We may use equation (1) to determine the rate at which the ions disappear when the ionizing agent is removed. Putting $q = 0$ in that equation we get $dn/\alpha t = \alpha n^2$.

Hence
$$n = n_0/(1 + n_0\alpha t) \qquad (3),$$

where n_0 is the number of ions when $t = 0$. Thus the number of ions falls to one-half its initial value in the time $1/n_0\alpha$. The quantity α is called the *coefficient of recombination*, and its value for different gases has been determined by Rutherford (*Phil. Mag.* 1897 [5], 44, p. 422), Townsend (*Phil. Trans.*, 1900, 193, p. 129), McClung (*Phil. Mag.*, 1902 [6], 3, p. 283), Langevin (*Ann. chim. phys.* [7], 28, p. 289), Retschinsky (*Ann. d. Phys.*, 1905, 17, p. 518), Hendred (*Phys. Rev.* 1905, 21, p. 314), Rümelin (*Phys. Zeits.*, ix. p. 657, 1908), Thirkill (*Proc. Roy. Soc.*, 87, p. 477, 1913), Erikson (*Phil. Mag.*, vi. 18 p. 328, 1909; 23, p. 747, 1912). The values of α/e, e being the charge on an ion in electrostatic measure as determined by these observers for different gases, is given in the following table:—

	Townsend	McClung	Langevin	Retschinsky	Hendred
Air	3,420	3,380	3,200	4,140	3,500
O_2	3,380	..	..	..	..
CO_2	3,500	3,490	3,400	..	..
H_2	3,020	2,940	..	..	..

The gases in these experiments were carefully dried and free from dust; the apparent value of α is much increased when dust or small drops of water are present in the gas, for then the ions get caught by the dust particles, the mass of a particle is so great compared with that of an ion that they are practically immovable under the action of the electric field, and so the ions clinging to them escape detection when electrical methods are used. Taking e as 4.77×10^{-10}, we see that α is about 1.6×10^{-6}, so that the number of recombinations in unit time between n positive and n negative ions in unit volume is $1.6 \times 10^{-6} n^2$. The kinetic theory of gases shows that with $2n$ molecules of air per cubic centimetre the number of collisions per second is $4 \times 10^{-10} n^2$ at a temperature of 0° C. Thus we see that the number of recombinations between oppositely charged ions is enormously greater than the number of collisions between the same number of neutral molecules. We shall see that the difference in size between the ion and the molecule is not nearly sufficient to account for the difference between the collisions in the two cases; the difference is due to the force between the oppositely charged ions, which drags ions into collisions which but for this force would have missed each other.

Several methods have been used to measure α. In one method air, exposed to some ionizing agent at one end of a long tube, is slowly sucked through the tube and the saturation current measured at different points along the tube. These currents are proportional to the values of n at the place of observation: if we know the distance of this place from the end of the tube when the gas was ionized and the velocity of the stream of gas, we can find t in equation (3), and knowing the value of n we can deduce the value of α from the equation

$$1/n_1 - 1/n_2 = \alpha(t_1 - t_2),$$

where n_1 n_2 are the values of n at the times t_1, t_2 respectively. In this method the tubes ought to be so wide that the loss of ions by diffusion to the sides of the tube is negligible. This method does not involve the mobility of the ions, *i.e.*, the speed they acquire under electric forces. Another method which has the same advantage is due to Rümelin. In this the gas is exposed continuously to the ionizing agent, while the electric field is applied to the gas by means of a rotating sector and is adjusted so as to be *zero* during one part of the revolution of the sector and great enough to produce saturation during the remainder. The current sent through the gas by this field is measured and from it the value of α can be calculated. There are other methods which involve the knowledge of the mobility of the ions; we shall defer the consideration of these methods until we have discussed this question.

In measuring the value of α it should be remembered that the theory of the methods supposes that the ionization is uniform throughout the gas. If the total ionization throughout a gas remains constant, but instead of being uniformly distributed is concentrated in patches, it is evident that the ions will recombine more quickly in the second case than in the first, and that the value of α will be different in the two cases. This probably explains the large values of α obtained by Retschinsky, who ionized the gas by the α rays from radium, a method which produces very patchy ionization.

Variation of α with the Pressure of the Gas.—This question was first investigated by Langevin (*Ann. Chem. Phys.*, 1903, 28, p. 287) who found that at low pressures α was less than at high, thus at the pressure of one-fifth of an atmosphere the value of α for air was about one-fifth of that at atmospheric pressure. He showed, too, that the value of α reached a maximum at a certain pressure—for air about two atmospheres— and fell away fairly rapidly with any further increase in pressure. A very valuable investigation of the effect of pressure on the value of α was made by Thirkill (*Proc. Roy. Soc.*, 88, p. 477, 1913), who showed that for pressures not exceeding one atmosphere α is very approximately a linear function of the pressure, the gases he investigated were air, carbon dioxide, carbon monoxide, sulphur dioxide and nitrous oxide.

Variation of α with Temperature.—The variation of α with temperature has been investigated for air, carbonic acid and hydrogen at constant density when ionized by α rays by Erikson (*Phil. Mag.*, vi. 18, p. 328, 1909; 23, p. 747, 1912) and for air at constant pressure ionized by X-rays by Phillips (*Proc. Roy. Soc.* A. 83, p. 246, 1910). It was found that over a very wide range of temperature α for hydrogen can be repre-

sented by a formula of the type $\alpha = C\theta^{-n}$ when θ is the absolute temperature and C a constant, and though such a formula does not hold for air and carbonic acid at temperatures much below 0° C, it represents the value of α with fair accuracy at higher temperatures. Erikson's experiments give $n = 2{\cdot}42$, $2{\cdot}35$, $2{\cdot}30$, for air, carbonic acid and hydrogen respectively, while Phillips (at constant pressure) finds $n = 2$.

Diffusion of the Ions.—The ionized gas acts like a mixture of gases, the ions corresponding to two different gases, the non-ionized gas to a third. If the concentration of the ions is not uniform, they will diffuse through the non-ionized gas in such a way as to produce a more uniform distribution. A very valuable series of determinations of the coefficient of diffusion of ions through various gases has been made by Townsend (*Phil. Trans.*, 1900, A, 193, p. 129). The method used was to suck the ionized gas through narrow tubes; by measuring the loss of both the positive and negative ions after the gases had passed through a known length of tube, and allowing for the loss by recombination, the loss by diffusion and hence the coefficient of diffusion could be determined. Salles, Franck and Westphal have used similar methods. Salles found that the material of which the tubes are made has no influence on the diffusion. The following tables give the values of the coefficients of diffusion D on the C.G.S. system of units.

Gas	*D* for +ions	*D* for −ions	Author
Air, dry	·028	·043	Townsend
,, ,,	·032	·042	Salles
,, ,,	·029	·045	Franck and Westphal
,, moist	·032	·035	Townsend
Oxygen, dry	·025	·0396	Townsend
,, ,,	·030	·041	Salles
,, moist	·0288	·0358	Townsend
Carbon dioxide, dry	·023	·026	Townsend
,, ,, ,,	·025	·026	Salles
,, ,, moist	·0245	·0255	Townsend
Hydrogen, dry	·123	·190	Townsend
,, moist	·128	·142	Townsend
Nitrogen, dry	·029	·0414	Salles

It is interesting to compare with these coefficients the values of D when various gases diffuse through each other. D for hydrogen through air is ·634, for oxygen through air ·177, for the vapour of isobutyl amide through air ·042. We thus see that the velocity of diffusion of ions through air is much less than that of the simple gas, but that it is quite comparable with that of the vapours of some complex organic compounds.

The preceding tables show that the negative ions diffuse more rapidly than the positive, especially in dry gases. The superior mobility of the negative ions was observed first by Zeleny (*Phil. Mag.*, 1898 [5], 46, p. 120), who showed that the velocity of the negative ions under an electric force is greater than that of the positive. It will be noticed that the difference between the mobility of the negative and the positive ions is much more pronounced in dry gases than in moist. The difference in the rates of diffusion of the positive and negative ions is the reason why ionized gas, in which, to begin with, the positive and negative charges were of equal amounts, sometimes becomes electrified even although the gas is not acted upon by electric forces. Thus, for example, if such gas be blown through narrow tubes, it will be positively electrified when it comes out, for since the negative ions diffuse more rapidly than the positive, the gas in its passage through the tubes will lose by diffusion more negative than positive ions and hence will emerge positively electrified. Zeleny showed that this effect does not occur when, as in carbonic acid gas, the positive and negative ions diffuse at the same rates. Townsend (*loc. cit.*) showed that the coefficient of diffusion of the ions is the same whether the ionization is produced by Röntgen rays, radioactive substances, ultra-violet light, or electric sparks. The ions produced by chemical reactions and in flames are much less mobile; thus, for example, Bloch (*Ann. chim. phys.*, 1905 [8], 4, p. 25) found that for the ions produced by drawing air over phosphorus the value of α/e was between 1 and 6 instead of over 3,000, the value when the air was ionized by Röntgen rays.

Velocity of Ions in an Electric Field.—The velocity of ions in an electric field, which is of fundamental importance in conduction, is very closely related to the coefficient of diffusion. Measurements of this velocity for ions produced by Röntgen rays have been made by Rutherford (*Phil. Mag.* [5], 44, p. 422), Zeleny (*Phil. Mag.* [5], 46, p. 120), Langevin (*Ann. Chim. Phys.*, 1903, 28, p. 289), Phillips (*Proc. Roy. Soc.* 78, A, p. 167), and Wellisch (*Phil. Trans.*, 1909, 209, p. 249). The ions produced by radioactive substance have been investigated by Rutherford (*Phil. Mag.* [5], 47, p. 109) and by Franck and Pohl (*Verh. deutsch. phys. Gesell.*, 1907, 9 p. 69), Tyndall and Grindley (*Proc. Roy. Soc.*, A, 110, p. 341; Laporte, C.R. 172, p. 1028, 1921; 182, pp. 620–781, 1926; 183, pp. 119–287), and the negative ions produced when ultra-violet light falls on a metal plate by Rutherford (*Proc. Camb. Phil. Soc.* 9, p. 401), Townsend and Tizard (*Proc. Roy. Soc.*, A, 87, p. 357, 1912), H. A. Wilson (*Phil. Trans.* 192, p. 409), Marx (*Ann. de Phys.* 11, p. 765); Moreau (*Journ. de Phys.* 4, 11, p. 558; *Ann. Chim. Phys.* 7, 30, p. 5) and Gold (*Proc. Roy. Soc.* 79, p. 43) have investigated the velocities of ions produced by putting various salts into flames; McClelland (*Phil. Mag.* 46, p. 29) the velocity of the ions in gases sucked from the neighbourhood of flames and arcs; Townsend (*Proc. Camb. Phil. Soc.* 9, p. 345) and Bloch (*loc. cit.*) the velocity of ions produced by chemical reaction; and Chattock (*Phil. Mag.* [5], 48, p. 401) and Franck (*Ann. der. Phys.*, 21, p. 972, 1908), the velocity of the ions produced when electricity escapes from a sharp needle point into a gas. Though so much work has been done on the mobility of the ions there are many points which are still unsettled. The experiments of the earlier observers were more discordant than could be accounted for by errors of observation; in some cases, indeed, they were contradictory. We know now that the mobility of the ions is profoundly affected by causes which at first sight appear trivial and may well have escaped specification in the earlier experiments. One of these causes is the age of the ions, the mobility of a freshly formed ion is often greater than that of an older one, a fact brought out clearly by Erikson's experiments; thus since the age of the ion influences its mobility, observers would obtain different results unless by chance it happened that the time which elapsed between the formation of the ion and the time that it came under observation was the same in the two cases. Another reason for the want of agreement is that, as we shall see, minute traces of an impurity in the gas may produce very large effects on the mobility.

Several methods have been employed to determine these velocities. The one most frequently employed is to find the electromotive intensity required to force an ion against the stream of gas moving with a known velocity parallel to the lines of electric force. Thus, of two perforated plane electrodes vertically over each other, suppose the lower to be positively, the upper negatively electrified, and suppose that the gas is streaming vertically downwards with the velocity V; then unless the upward velocity of the positive ion is greater than V, no positive electricity will reach the upper plate. If we increase the strength of the field between the plates, and hence the upward velocity of the positive ion, until the positive ions just begin to reach the upper plate, we know that with this strength of field the velocity of the positive ion is equal to V. By this method, which has been used by Rutherford, Zeleny, H. A. Wilson and Erikson the velocity of ions in fields of various strengths has been determined.

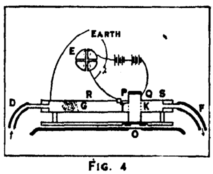

FIG. 4

The arrangement used by Zeleny is represented in fig. 4. P and Q are square brass plates. They are bored through their centres, and to the openings the tubes R and S are attached, the space between the plates being covered in so as to form a closed box. K is a piece of wire gauze completely covering the opening in Q; T is an insulated piece of wire gauze nearly but not quite filling the opening in the plate P, and connected with one pair of quadrants of an electrometer E. A plug of glass wool G filters

out the dust from a stream of gas which enters the vessel by the tube D and leaves it by F; this plug also makes the velocity of the flow of the gas uniform across the section of the tube. The Röntgen rays to ionize the gas were produced by a bulb at O, the bulb and coil being in a lead-covered box, with an aluminium window through which the rays passed. Q is connected with one pole of a battery of cells, P and the other pole of the battery are put to earth. The changes in the potential of T are due to ions giving up their charges to it. With a given velocity of air-blast the potential of T was found not to change unless the difference of potential between P and Q exceeded a critical value. The field corresponding to this critical value thus made the ions move with the known velocity of the blast.

Another method which has been employed by Rutherford and McClelland is based on the action of an electric field in destroying the conductivity of gas streaming through it. Suppose that BAB, DCD (fig. 5) are a system of parallel plates boxed so that a stream of gas, after flowing between BB, passes between DD without loss of gas in the interval. Suppose the plates DD

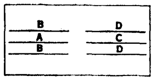

FIG. 5

are insulated, and connected with one pair of quadrants of an electrometer, by charging up C to a sufficiently high potential we can drive all the positive ions which enter the system DCD against the plates D; this will cause a deflexion of the electrometer, which in one second will be proportional to the number of positive ions which have entered the system in that time. If we charge A up to a high potential, B being put to earth, we shall find that the deflexion of the electrometer connected with DD is less than it was when A and B were at the same potential, because some of the positive ions in their passage through BAB are driven against the plates B. If u is the velocity along the lines of force in the uniform electric field between A and B, and t the time it takes for the gas to pass through BAB, then all the positive ions within a distance ut of the plates B will be driven up against these plates, and thus, if the positive ions are equally distributed through the gas, the number of positive ions which emerge from the system when the electric field is on will bear to the number which emerge when the field is off the ratio of $1-ut/l$ to unity, where l is the distance between A and B. This ratio is equal to the ratio of the deflexions in one second of the electrometer attached to D, hence the observations of this instrument give $1-ut/l$. If we know the velocity of the gas and the length of the plates A and B, we can determine t, and since l can be easily measured, we can find u, the velocity of the positive ion in a field of given strength. By charging A and C negatively instead of positively we can arrive at the velocity of the negative ion. In practice it is more convenient to use cylindrical tubes with coaxial wires instead of the systems of parallel plates, though in this case the calculation of the velocity of the ions from the observations is a little more complicated, inasmuch as the electric field is not uniform between the tubes.

A method which gives very accurate results, though it is only applicable in certain cases, is the one used by Rutherford to measure the velocity of the negative ions produced close to a metal plate by the incidence on the plate of ultra-violet light.

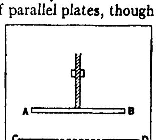

FIG. 6

The principle of the method is as follows:—AB (fig. 6) is an insulated horizontal plate of well-polished zinc, which can be moved vertically up and down by means of a screw; it is connected with one pair of quadrants of an electrometer, the other pair of quadrants being put to earth. CD is a base-plate with a hole EF in it; this hole is covered with fine wire gauze, through which ultraviolet light passes and falls on the plate AB. The plate CD is connected with an alternating current dynamo, which produces a simply-periodic potential difference between AB and CD, the other pole being put to earth. Suppose that at any instant the plate CD is at a higher potential than AB, then the negative ions from AB will move towards CD, and will continue to do so as long as the potential of CD is higher than that of AB. If, however, the potential difference changes sign before the negative ions reach CD, these ions will go back to AB. Thus AB will not lose any negative charge unless the distance between the plates AB and CD is less than the distance traversed by the negative ion during the time the potential of CD is higher than that of AB. By altering the distance between the plates until CD just begins to lose a negative charge, we find the velocity of the negative ion under unit electromotive intensity. Suppose the difference of potential between AB and CD is equal to $a \sin pt$, then if d is the distance between the plates the electric intensity is equal to $a \sin pt/d$; if we suppose the velocity of the ion is proportional to the electric intensity; and if u is the velocity for unit electric intensity, the velocity of the negative ion will be $ua \sin pt/d$. Hence if x represent the distance of the ion from AB

$$\frac{dx}{dt} = \frac{ua}{d}\sin pt$$

$$x = \frac{ua}{pd}(1-\cos pt), \text{ if } x=0 \text{ when } t=0.$$

Thus the greatest distance the ion can get from the plate is equal to $2au/pd$, and, if the distance between the plates is gradually reduced to this value, the plate AB will begin to lose a negative charge; hence when this happens

$$d=2au/pd, \quad \text{or } u=pd^2/2a,$$

an equation by means of which we can find u.

Instead of using a harmonically varying field we may by a rotating commutation apply a constant force for a certain time and then reverse the force taking care that the time it is applied after reversal is longer than the other time. Unless the ion can travel across the distance between the plates before the field is reversed the electrometer will not receive a charge; this gives the means of finding the mobility of the ions.

In this form the method is not applicable when ions of both signs are present. Franck and Pohl (*Verh. deutsch. physik. Gesell.* 1907, 9 p. 69) have by a slight modification removed this restriction. The modification consists in confining the ionization to a layer of gas below the gauze EF. If the velocity of the positive ions is to be determined, these ions are forced through the gauze by applying to the ionized gas a small constant electric force acting upwards; if negative ions are required, the constant force is reversed. After passing through the gauze the ions are acted upon by alternating forces as in Rutherford's method. Loeb (*Phys. Review*, XXI., p. 720, 1923) has shown that the disturbance of the electric field due to spreading of the lines of force due to the subsidiary field through the gauze may involve serious corrections to the simple theory.

Langevin (*Ann. chim. phys.*, 1903, 28, p. 289) devised a method of measuring the velocity of the ions which has been extensively used; it has the advantage of not requiring the rate of ionization to remain uniform. The general idea is as follows. Suppose that we expose the gas between two parallel plates A, B, to Röntgen rays or some other ionizing agent, then stop the rays and apply a uniform electric field to the region between the plates. If the force on the positive ion is from A to B, the plate B will receive a positive charge of electricity. After the electric force has acted for a time T reverse it. B will now begin to receive negative electricity and will go on doing so until the supply of negative ions is exhausted. Let us consider how the quantity of positive electricity received by B will vary with T. To fix our ideas, suppose the positive ions move more slowly than the negative; let T_2 and T_1 be respectively the times taken by the positive and negative ions to move under the electric field through a distance equal to AB, the distance between the planes. Then if T is greater than T_2 all the ions will have been driven from between the plates before the field is reversed, and therefore the positive charge received by B will not depend upon T. Next let T be less than T_2 but greater than T_1; then at the time when the field is reversed all the negative ions will have been driven from between the plates, so that the positive charge received by B will not be neutralized by the arrival of fresh ions coming to it after the reversal of the field. The number of positive ions driven against the plate

B will be proportional to T. Thus if we measure the value of the positive charge on B for a series of values of T, each value being less than the preceding, we shall find that until T reaches a certain value the charge remains constant, but as soon as we reduce the time below this value the charge diminishes. The value of T when the diminution in the field begins is T_2, the time taken for a positive ion to cross from A to B under the electric field; thus from T_2 we can calculate the velocity of the positive ion in this field. If we still further diminish T, we shall find that we reach a value when the diminution of the positive charge on B with the time suddenly becomes much more rapid; this change occurs when T falls below T_1 the time taken for the negative ions to go from one plate to the other, for now when the field is reversed there are still some negative ions left between the plates, and these will be driven against B and rob it of some of the positive charge it had acquired before the field was reversed. By observing the time when the increase in the rate of diminution of the positive charge with the time suddenly sets in we can determine T_1, and hence the velocity of the negative ions.

The velocity of the ions produced by the discharge of electricity from a fine point was determined by Chattock by an entirely different method. In this case the electric field is so strong and the velocity of the ion so great that the preceding methods are not applicable. Suppose P represents a vertical needle discharging electricity into air, consider the force acting on the ions included between two horizontal planes A, B. If P is the density of the electrification, and Z the vertical component of the electric intensity, F, the resultant force on the ions between A and B, is vertical and equal to

$$\iiint Z\rho\,dx\,dy\,dz.$$

Let us suppose that the velocity of the ion is proportional to the electric intensity, so that if w is the vertical velocity of the ions, which are supposed all to be of one sign, $w=RZ$.

Substituting this value of Z, the vertical force on the ions between A and B is equal to

$$\frac{1}{R}\iiint w\rho\,dx\,dy\,dz.$$

But $\iint wp\,dx\,dy=\iota$, where ι, is the current streaming from the point. This current, which can be easily measured by putting a galvanometer in series with the discharging point, is independent of z, the vertical distance of a plane between A and B below the charging point. Hence we have

$$F=\frac{\iota}{R}\int dz=\frac{\iota}{R}.z.$$

This force must be counterbalanced by the difference of gaseous pressures over the planes A and B; hence if p_B and p_A denote respectively the pressures over B and A, we have

$$p_B-p_A=\frac{\iota}{R}z.$$

Hence by the measurement of these pressures we can determine R, and hence the velocity with which an ion moves under a given electric intensity.

There are other methods of determining the velocities of the ions, but as these depend on the theory of the conduction of electricity through a gas containing charged ions, we shall consider them in our discussion of that theory.

By the use of these methods it has been shown that the velocities of the ions in a given gas are the same whether the ionization is produced by Röntgen rays, radioactive substances, ultra-violet light, or by the discharge of electricity from points. When the ionization is produced by chemical action the ions are very much less mobile, moving in the same electric field with a velocity less than one-thousandth part of the velocity of the first kind of ions. On the other hand, as we shall see later, the velocity of the negative ions in flames is enormously greater than that of even the first kind of ion under similar electric fields and at the same pressure. But when these negative ions get into the cold part of the flame, they move sluggishly with velocities of the order of those possessed by the second kind. The results of the various determinations of the velocities of the ions are given in the following table. The velocities are in centimetres per second under an electric force of one volt per centimetre, the pressure of the gas being 1 atmosphere. V+ denotes the velocity of the positive ion, V− that of the negative. V is the mean velocity of the positive and negative ions.

Velocities of Ions: Ions Produced by Röntgen Rays

Gas	V+	V−	V	Observer

Ions in Gases Sucked from Flames

Velocities varying from ·04 to ·23 McClelland

Ions in Flames Containing Salts

Negative ions	12,000 cm./sec./volt/cm.	Gold
	7,200–11,900	Wilckens
	10,000	H. A. Wilson
Positive ions for	2·5	Andrade
Salts of alkali metals	1	H. A. Wilson

The much larger values, of the order 100 cm./sec./volt/cm., obtained by earlier workers for the velocity of positive ions in flames seem very doubtful.

Ions Liberated by Chemical Action

Velocities of the order of 0·0005 cm./sec. Bloch

Ions from Point Discharge

Hydrogen	5·4	7·43	6·41	Chattock
Carbonic acid	0·83	0·925	0·88	„
Air	1·32	1·80	1·55	„
Oxygen	1·30	1·85	1·57	„

It will be seen from this table that the greater mobility of the negative ions is very much more marked in the case of the lighter and simpler gases than in that of the heavier and more complicated ones; with the vapours of organic substances there seems but little difference between the mobilities of the positive and negative ions; indeed in one or two cases the positive seem slightly but very slightly the more mobile of the two. In

the case of the simple gases the difference is much greater when the gases are dry than when they are moist. It has been shown by direct experiment that the velocities are directly proportional to the electric force.

Variation of Velocities with Pressure.—Until the pressure gets low the velocities of the ions, negative as well as positive, vary inversely as the pressure. Langevin (*loc. cit.*) was the first to show that at very low pressures the velocity of the negative ions increases more rapidly as the pressure is diminished than this law indicates. If the nature of the ion did not change with the pressure, the kinetic theory of gases indicates that the velocity would vary inversely as the pressure, so that Langevin's results indicate a change in the nature of the negative ion when the pressure is diminished below a certain value. Kovarik has determined the mobility of the negative ions in air and CO_2 down to a pressure of 1 cm. and finds that at these low pressures the value of pV where p is the pressure and V the mobility increases rapidly as the pressure diminishes. The increase in the case of $pV-$ indicates that the structure of the negative ion gets simpler as the pressure is reduced. Wallisch, in some experiments made at the Cavendish laboratory, found that the diminution in the value of $pV-$ at low pressures is much more marked in some gases than in others, and in some gases he failed to detect it; but it must be remembered that it is difficult to get measurements at pressures of only a few millimetres, as the amount of ionization is so exceedingly small at such pressures that the quantities to be observed are hardly large enough to admit of accurate measurements by the methods available at higher pressures.

The key to the behaviour of the negative ion is the fact that it begins by being an electron and does not unite with a molecule of the gas to form a normal ion until it has made a large number of collisions with the molecules of the gas through which it is passing. This number has been determined by Loeb (*Phys. Rev.*, 17, p. 89, 1921; *Phil. Mag.*, 43, p. 229, 1922), who finds that it is independent of the pressure of the gas but varies enormously from one gas to another; thus in pure nitrogen, helium, argon and carbon monoxide in which this number is infinity the electrons never unite with the molecules; in CO_2 the number is about three millions, in air about 30 thousand, in oxygen three thousand and in chlorine less than two thousand. When in the electronic state the mobility is very high. Thus Franck found that the mobility of the negative ion in very pure argon was 206, while if 1% of oxygen was added the mobility fell to 1·7 and in pure helium Franck and Gehlhoff found that the mobility of the negative ion was 509. Haines obtains still larger values for nitrogen and Loeb has shown that these high mobilities vary with the strength of the electric field. The life of the electron is much reduced by the presence of a trace of water vapour.

Most measurements of the mobilities of ions amount to measuring the time taken by the ion to pass through a given length in the gas; if the ion begins as an electron the mobility measured will be a mean value depending on the proportion of the time it is an electron to the time of transit. If the pressure is lowered the time in the electronic state is increased, since the number of collisions the electron makes before leaving this state is unaltered by the change in pressure, while the time between each collision varies inversely as the pressure. The time of transit will be less at low pressures than at high, so that the proportion between the time in the electronic state and the time of transit will vary inversely as the square of the pressure. Thus the high mobility of the electron will produce much greater increase in the mobility at low pressures than at high, and will account for the effects observed by Langevin and Kovarik. It will also account for the fact that the rapid increase of the mobility at low pressures is much more marked in gases which have been carefully dried than in those which contain a trace of water vapour, and that these mobilities depend upon the strength of the electric field.

Effect of Temperature on the Velocity of the Ions.—Phillips (*Proc. Roy. Soc.*, 1906, 78, p. 167) investigated, using Langevin's method, the velocities of the + and − ions through air at atmospheric pressure at temperatures ranging from that of boiling liquid air to 411° C; R_1 and R_2 are the velocities of the + and − ions respectively when the force is a volt per centimetre.

R_1	R_2	Temperature absolute
2·00	2·495	411°
1·95	2·40	399°
1·85	2·30	383°
1·81	2·21	373°
1·67	2·125	348°
1·60	2·00	333°
1·39	1·785	285°
0·945	1·23	209°
0·235	0·235	94°

We see that except in the case of the lowest temperature, that of liquid air, where there is a great drop in the velocity, the velocities of the ions are proportional to the absolute temperature; since the pressure is constant this implies that at constant density the mobility is independent of the temperature. On the hypothesis of an ion of constant size we should, from the kinetic theory of gases, expect the velocity to be proportional to the square root of the absolute temperature, if the charge on the ion did not affect the number of collisions between the ion and the molecules of the gas through which it is moving. If the collisions were brought about by the electrical attraction between the ions and the molecules, the velocity would be proportional to the absolute temperature. The mobility of ions at high temperatures such as those which occur in flames has been the subject of several experiments. The first determination was made in 1899 by H. A. Wilson (*Phil. Tran.*, A, 192, p. 499) who measured the mobility of positive ions in flames containing the vapour of alkali metals and found that it was 62 cm./sec. Andrade, in 1912 (*Phil. Mag.*, 6, 23, 865) by a different method obtained the value 2·5 cm./sec. for strontium ions in a flame. H. A. Wilson, in a later investigation (*Phil. Trans.*, A, 216, p. 63, 1916) came to the conclusion that his earlier values were much too high and estimated the true value as 1 cm./sec., which is of the same order as that obtained by Andrade.

The great effect of temperature is also shown in some experiments of McClelland (*Phil. Mag.* [5], 46, p. 29) on the velocities of the ions in gases drawn from Bunsen flames and arcs; he found that these depended upon the distance the gas had travelled from the flame. Thus, the velocity of the ions at a distance of 5·5 cm. from the Bunsen flame when the temperature was 230° C was ·23 cm./sec. for a volt per centimetre; at a distance of 10 cm. from the flame when the temperature was 160° C the velocity was ·21 cm./sec.; while at a distance of 14·5 cm. from the flame when the temperature was 105° C the velocity was only ·04 cm./sec. If the temperature of the gas at this distance from the flame was raised by external means, the velocity of the ions increased.

We can derive some information as to the constitution of the ions by calculating the velocity with which a molecule of the gas would move in the electric field if it carried the same charge as the ion. From the theory of the diffusion of gases, as developed by Maxwell, we know that if the particles of a gas A are surrounded by a gas B, then, if the partial pressure of A is small, the velocity u with which its particles will move when acted upon by a force Xe is given by the equation

$$u=\frac{Xe}{(p_1/N_1)}D,$$

where D represents the coefficient of inter-diffusion of A into B, and N_1 the number of particles of A per cubic centimetre when the pressure due to A is p_1. Let us calculate by this equation the velocity with which a molecule of hydrogen would move through hydrogen if it carried the charge carried by an ion, which we shall prove shortly to be equal to the charge carried by an atom of hydrogen in the electrolysis of solutions. Since p_1/N_1 is independent of the pressure, it is equal to Π/N, where Π is the atmospheric pressure and N the number of molecules in the cubic centimetre of gas at atmospheric pressure. Now $Ne=1{\cdot}22\times10^{10}$, if e is measured in electrostatic units; $\Pi=10^6$ and D in this case is the coefficient of diffusion of hydrogen into itself, and is equal to

1·7. Substituting these values we find

$$u = 1{\cdot}97 \times 10^4 X.$$

If the potential gradient is 1 volt per centimetre, $X = 1/300$. Substituting this value for X, we find $u = 66$ cm./sec., for the velocity of a hydrogen molecule. We have seen that the velocity of the ion in hydrogen is only about 5 cm./sec., so that the ion moves more slowly than it would if it were a single molecule. One way of explaining this is to suppose that the ion is bigger than the molecule, and is in fact an aggregation of molecules, the charged ion acting as a nucleus around which molecules collect like dust round a charged body. This view is supported by the effect produced by moisture in diminishing the velocity of the negative ion, for, as C. T. R. Wilson (*Phil. Trans.* 193, p. 289) has shown, moisture tends to collect round the ions, and condenses more easily on the negative than on the positive ion. In connection with the velocities of ions in the gases drawn from flames, we find other instances which suggest that condensation takes place round the ions. An increase in the size of the system is not, however, the only way by which the velocity might fall below that calculated for the hydrogen molecule, for we must remember that the hydrogen molecule, whose coefficient of diffusion is 1·7, is not charged, while the ion is. The forces exerted by the ion on the other molecules of hydrogen are not the same as those which would be exerted by a molecule of hydrogen, and as the coefficient of diffusion depends on the forces between the molecules, the coefficient of diffusion of a charged molecule into hydrogen might be very different from that of an uncharged one.

Wellisch (*loc. cit.*) has shown that the effect of the charge on the ion is sufficient in many cases to explain the small velocity of the ions, even if there were no aggregation.

Mixture of Gases.—The ionization of a mixture of gases raises some very interesting questions. If we ionize a mixture of two very different gases, say hydrogen and carbonic acid, and investigate the nature of the ions by measuring their velocities, the question arises, shall we find two kinds of positive and two kinds of negative ions moving with different velocities, as we should do if some of the positive ions were positively charged hydrogen molecules, while others were positively charged molecules of carbonic acid; or shall we find only one velocity for the positive ions and one for the negative? Many experiments have been made on the velocity of ions in mixtures of two gases, but as yet no evidence has been found of the existence of two different kinds of either positive or negative ions in such mixtures, although some of the methods for determining the velocities of the ions, especially Langevin's, ought to give evidence of this effect, if it existed. The experiments seem to show that the mobilities depend on the nature of the gas through which the ions move but not upon the nature of the ions themselves. Thus Blanc found that the mobility of an ion made in CO_2 and driven through air was the same as that of an ion made in the air itself.

Grindley and Tyndall (*Phil. Mag.*, 48, p. 711, 1924) show that the mobility through air of ions formed in H_2,NH_3,$CO_2$$(C_2H_5)_2O$; and $CHCl_3$ was practically the same as that of ordinary air ions. Erikson finds that argon, CO_2, and H_2 ions in air have the same mobility as air ions. Further, Rutherford has shown that the mobility of the heavy "recoil atoms" from radioactive substances, which have an atomic weight greater than 200 have in air the same mobility as air atoms. This is important because the radioactive nature of the ions was tested at the end of their path: so that this disposes of the attractive hypothesis that the charge keeps passing from one molecule to another so that however the ion may start, it is soon a molecule of the gas through which it is passing. Wellisch made very important experiments on mixed gases, *e.g.*, mixtures of SO_2 and O_2 and of ethyl ether and air, and found that he could only detect one type of positive and one of negative ions. The only exception to this result seems to be the fact discovered by Erikson that in air positive ions when they are "old," *i.e.*, after some tenths of a second has elapsed since their formation, have only a mobility of about ·7 of that of newly formed positive ions, he found no difference between young and old negative ions.

The most important results which have emerged from experiments on the mobility of the ions are:—

1. The mobility of the ions, especially in the lighter gases, is much less than it would be if the ion consists of a single molecule having the same free path as an uncharged molecule.
2. The mobility of the ions depends only on the gas through which they move, so that though in a mixture of gases there may be ions of different kinds, all the ions of the same sign have the same mobility. An exception to this is the discovery by Erikson that aged ions have a smaller mobility than fresh ones.
3. In the lighter gases the mobility of the negative ions is greater than that of the positive.
4. The mobility of the negative ions is diminished by traces of the vapours of water and various alcohols.
5. For positive ions the product of the mobility and pressure is constant over a very wide range of pressure; for negative ions, however, the product at low pressure rapidly increases as the pressure diminishes.
6. Experiments with heavy ions from radioactive elements show that these have the normal mobility and retain their identity whilst in the electric field.

It is helpful to consider the various conditions which on the kinetic theory of gases would affect the mobility of the ions. The mobility of the ion is proportional to the coefficient of diffusion of the ion through the gas and this coefficient is equal to

$$\epsilon\lambda \int \frac{1}{\pi h}\left(\frac{1}{m_1}+\frac{1}{m_2}\right)$$

ϵ is a numerical constant, λ the free path of the iron through the gas; m_1, m_2 the masses of the ion and molecule respectively and $h = RT/2$ where T is the absolute temperature and R the gas constant. First consider the effect of the electric charge on the free path, supposing for the moment that the mass of the ion is the same as that of a molecule. The attraction between an ion and a molecule will in consequence of the charge be greater than that between uncharged molecules; the ion and the molecules will be dragged together and the free path of the ion less than that of the molecule. Thus λ will be less for the ion than for the molecule and the coefficient of diffusion less. If λ^1 is the free path of the ion, λ that of the uncharged molecule, w the work required to separate an ion from a molecule with which it is in contact, we can show that if the form between the ion and the molecule varies inversely as the fifth power of the distance

$$\frac{\lambda^1 = \lambda}{1+\alpha(w/RT)^{1/2}}$$

when α is a numerical constant. We see from this expression that if we are to explain the slow diffusion of the ion by the charge alone, w must be large compared with RT, *i.e.*, the work required to separate an ion from a molecule must be large compared with the kinetic energy of a molecule due to thermal agitation. It follows, however, from the principles of thermodynamics that in this case the ions will unite with the molecules and form aggregates, and thus that any considerable diminution in the free path is inconsistent with the ions being monomolecular.

Let us turn now to the effect of mass upon the mobility of the ion; we see from the expression for the coefficient of diffusion that the mobility is proportional to

$$\sqrt{\frac{1}{m_1}+\frac{1}{m_2}}$$

Thus when the mass of the ion, is one, two, three—or an infinite number of times that of the molecule the mobilities are in the ratio 1·41, 1·22, 1·15–1. Though these differences are not very large they are much greater than is consistent with the experimental fact that there is only one mobility for all positive and another for all negative in the same gas. While the mobility of a light ion through a heavy gas will be much greater than that of one formed by a molecule of this gas, thus from the formula the mobility of a hydrogen ion through methyl iodide would be six times that of a methyl iodide ion. We are forced to the conclusion that the ions cannot remain unaltered during their path through

the gas, but must pass through various phases in which they have different mobilities, and that the mobility measured by the usual methods is an average value and not its value in any particular phase.

Recombination.—Several methods enable us to deduce the coefficient of recombination of the ions when we know their velocities. Perhaps the simplest of these consists in determining the relation between the current passing between two parallel plates immersed in ionized gas and the potential difference between the plates. For let q be the amount of ionization, *i.e.*, the number of ions produced per second per unit volume of the gas, A the area of one of the plates, and d the distance between them; then if the ionization is constant through the volume, the number of ions of one sign produced per second in the gas is qAd. Now if i is the current per unit area of the plate and e the charge on an ion, iA/e ions of each sign are driven out of the gas by the current each second. In addition to this source of loss of ions there is the loss due to the recombination; if n is the number of positive or negative ions per unit volume, then the number which recombine per second is αn^2 per cubic centimetre, and if n is constant through the volume of the gas, as will approximately be the case if the current through the gas is only a small fraction of the saturation current, the number of ions which disappear per second through recombination is $\alpha n^2 \cdot Ad$. Hence, since when the gas is in a steady state the number of ions produced must be equal to the number which disappear, we have

$$qAd = iA/e + \alpha n^2 \cdot Ad,$$

$$q = i/ed + \alpha n^2.$$

If u_1 and u_2 are the velocities with which the positive and negative ions move, nu_1e and nu_2e are respectively the quantities of positive electricity passing in one direction through unit area of the gas per second, and of negative in the opposite direction, hence

$$i = nu_1e + nu_2e.$$

If X is the electric force acting on the gas, k_1 and k_2 the velocities of the positive and negative ions under unit force, $u_1 = k_1X$, $u_2 = k_2X$; hence

$$n = i/(k_1+k_2)Xe,$$

and we have

$$q = \frac{i}{ed} + \frac{\alpha i^2}{(k_1+k_2)^2e^2X^2}$$

But qed is the saturation current per unit area of the plate; calling this I, we have

$$I - i = \frac{d\alpha i^2}{e(k_1+k_2)^2X^2}$$

or

$$\frac{\alpha}{e} = X^2(I-i)\ (k_1+k_2)^2/di^2$$

Hence if we determine corresponding values of X and i we can deduce the value of α/e if we also know (k_1+k_2). The value of I is easily determined, as it is the current when X is very large. The preceding result only applies when i is small compared with I, as it is only in this case that the values of n and X are uniform throughout the volume of the gas. Another method which answers the same purpose is due to Langevin (*Ann. Chim. Phys.*, 1903, 28, p. 289); it is as follows. Let A and B be two parallel planes immersed in a gas, and let a slab of the gas bounded by the planes a, b parallel to A and B be ionized by an instantaneous flash of Röntgen rays. If A and B are at different electric potentials, then all the positive ions produced by the rays will be attracted by the negative plate and all the negative ions by the positive, if the electric field were exceedingly large they would reach these plates before they had time to recombine, so that each plate would receive N_0 ions if the flash of Röntgen rays produced N_0 positive and N_0 negative ions. With weaker fields the number of ions received by the plates will be less as some of them will recombine before they can reach the plates. We can find the number of ions which reach the plates in this case in the following way:—In consequence of the movement of the ions the slab of ionized gas will broaden out and will consist of three portions, one in which there are nothing but positive ions,—this is on the side of the negative plate,—another on the side of the positive plate in which there are nothing but negative ions, and a portion between these in which there are both positive and negative ions; it is in this layer that recombination takes place, and here if n is the number of positive or negative ions at the time t after the flash of Röntgen rays,

$$n = n_0/(1+\alpha n_0 t).$$

With the same notation as before, the breadth of either of the outer layers will in time dt increase by $X(k_1+k_2)dt$, and the number of ions in it by $X(k_1+k_2)ndt$; these ions will reach the plate, the outer layers will receive fresh ions until the middle one disappears, which it will do after a time $l/X(k_1+k_2)$, where l is the thickness of the slab ab of ionized gas; hence N, the number of ions reaching either plate, is given by the equation

$$N = \int_0^{l/X(k_1+k_2)} \frac{n_0X(k_1+k_2)}{1+n_0\alpha t}\,dt = \frac{X(k_1+k_2)}{\alpha}\log\left(1+\frac{n_0\alpha l}{X(k_1+k_2)}\right).$$

If Q is the charge received by the plate,

$$Q = Ne = \frac{X}{4\pi\epsilon}\log\left(1+\frac{Q_0\epsilon}{4\pi X}\right),$$

where $Q_0 = n_0le$ is the charge received by the plate when the electric force is large enough to prevent recombination, and $\epsilon = \alpha 4e(k_1+k_2)$. We can from this result deduce the value of ϵ and hence the value of α when k_1+k_2 is known.

Distribution of Electric Force When a Current Is Passing Through an Ionized Gas.—Let the two plates be at right angles to the axis of x; then we may suppose that between the plates the electric intensity X is everywhere parallel to the axis of x. The velocities of both the positive and negative ions are assumed to be proportional to X. Let k_1X, k_2X represent these velocities respectively; let n_1, n_2 be respectively the number of positive and negative ions per unit volume at a point fixed by the co-ordinate x; let q be the number of positive or negative ions produced in unit time per unit volume at this point; and let the number of ions which recombine in unit volume in unit time be αn_1n_2; then if e is the charge on the ion, the volume density of the electrification is $(n_1-n_2)e$, hence

$$\frac{dX}{dx} = 4\pi(n_1-n_2)e. \qquad (1)$$

If I is the current through unit area of the gas and if we neglect any diffusion except that caused by the electric field,

$$n_1ek_1X + n_2ek_2X = I. \qquad (2)$$

From equations (1) and (2) we have

$$n_1e = \frac{1}{k_1+k_2}\left(\frac{I}{X} + \frac{k_2}{4\pi}\frac{dX}{dx}\right), \qquad (3)$$

$$n_2e = \frac{1}{k_1+k_2}\left(\frac{I}{X} - \frac{k_1}{4\pi}\frac{dX}{dx}\right), \qquad (4)$$

and from these equations we can, if we know the distribution of electric intensity between the plates, calculate the number of positive and negative ions.

In a steady state the number of positive and negative ions in unit volume at a given place remains constant, hence neglecting the loss by diffusion, we have

$$\frac{d}{dx}(k_1n_1X) = q - \alpha n_1n_2 \qquad (5)$$

$$-\frac{d}{dx}(k_2n_2X) = q - \alpha n_1n_2. \qquad (6)$$

If k_1 and k_2 are constant, we have from (1), (5) and (6)

$$\frac{d^2X^2}{dx^2} = 8\pi e(q-\alpha n_1n_2\left(\frac{1}{k_1}+\frac{1}{k_2}\right), \qquad (7)$$

an equation which is very useful, because it enables us, if we know the distribution of X^2, to find whether at any point in the

gas the ionization is greater or less than the recombination of the ions. We see that $q-\alpha n_1n_2$, which is the excess of ionization over recombination, is proportional to d^2X^2/dx^2. Thus when the ionization exceeds the recombination, *i.e.*, when $q-\alpha n_1n_2$ is positive, the curve for X^2 is convex to the axis of x, while when the recombination exceeds the ionization the curve for X^2 will be concave to the axis of x. Thus, for example, fig. 7 represents the curve for X^2 observed by Graham (*Wied. Ann.* 64, p. 49) in a tube through which a steady current is passing. Interpreting it by equation (7), we infer that ionization was much in excess of recombination at A and B, slightly so along C, while along D the recombination exceeded the ionization. Substituting in equation (7) the values of n_1, n_2 given in (3), (4), we get

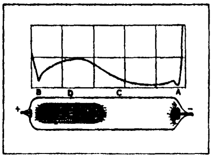

FIG. 7

$$\frac{d^2X^2}{dx^2}=8\pi e\left[q-\frac{\alpha}{e^2X^2(k_1+k_2)^2}\left(I+\frac{k_2}{8\pi}\frac{dX^2}{dx}\right)\left(I-\frac{k_2}{8\pi}\frac{dX^2}{dx}\right)\right]\left(\frac{1}{k_1}+\frac{1}{k_2}\right) \qquad (8).$$

This equation can be solved (*see* Thomson, *Phil. Mag.* xlvii. p. 253), when q is constant and $k_1=k_2$. From the solution it appears that if X_1 be the value of x close to one of the plates, and X_0 the value midway between them.

$$X_1/X_0=\beta^{-\frac{\beta}{2(1-\beta)}}$$

where $\beta=8\pi ek_1/\alpha$.

Since $e=4\cdot77\times10^{-10}$, $\alpha=1\cdot6\times10^{-6}\times10^{-6}$, and k^1 for air at atmospheric pressure $=520$, β is about 3·9 for air at atmospheric pressure and it becomes much greater at lower pressures.

Thus X_1/X_0 is always greater than unity, and the value of the ratio increases from unity to infinity as β increases from zero to infinity. As β does not involve either q or I, the ratio of X_1 to X_0 is independent of the strength of the current and of the intensity of the ionization.

No general solution of equation (8) has been found when k_1 is not equal to k_2, but we can get an approximation to the solution when q is constant. The equations (1), (2), (3), (4) are satisfied by the values—

$$n_1=n_2=(q/\alpha)^{\frac{1}{2}}$$

$$k_1n_1Xe=\frac{k_1}{k_1+k_2}I,$$

$$k_2n_2Xe=\frac{k_2}{k_1+k_2}I,$$

$$X=\left(\frac{\alpha}{q}\right)^{\frac{1}{2}}\frac{I}{e(k_1+k_2)}.$$

These solutions cannot, however, hold right up to the surface of the plates, for across each unit of area, at a point P, $k_1I/(k_1+k_2)e$ positive ions pass in unit time, and these must all come from the region between P and the positive plate. If λ is the distance of P from this plate, this region cannot furnish more than $q\lambda$ positive ions, and only this number if there are no recombinations. Hence the solution cannot hold when $q\lambda$ is less than $k_1I/(k_1+k_2)e$, or where λ is less than $k_1I/(k_1+k_2)qe$.

Similarly the solution cannot hold nearer to the negative plate than the distance $k_2I/(k_1+k_2)qe$.

The force in these layers will be greater than that in the middle of the gas, and so the loss of ions by recombination will be smaller in comparison with the loss due to the removal of the ions by the current. If we assume that in these layers the loss of ions by recombination can be neglected, we can by the method of the next article find an expression for the value of the electric force at any point in the layer. This, in conjunction with the value $X_0=\left(\frac{\alpha}{q}\right)^{\frac{1}{2}}\frac{I}{e(k_1+k_2)}$ for the gas outside the layer, will give the value of X at any point between the plates. It follows from this investigation that if X_1 and X_2 are the values of X at the positive and negative plates respectively, and X_0 the value of X outside the layer,

$$X_1=X_0\left(1+\frac{k_1}{k_2}\frac{1}{\epsilon}\right)^{\frac{1}{2}},\quad X_2=X_0\left(1+\frac{k_2}{k_1}\frac{1}{\epsilon}\right)^{\frac{1}{2}},$$

where $\epsilon=\alpha/4\pi e(k_1+k_2)$. Langevin found that for air at a pressure of 152 mm. $\epsilon=0\cdot01$, at 375 mm. $\epsilon=0\cdot06$, and at 760 mm. $\epsilon=0\cdot27$. Thus at fairly low pressures $1/\epsilon$ is large, and we have approximately

$$X_1=X_0\left(\frac{k_1}{k_2}\right)^{\frac{1}{2}}\frac{1}{\sqrt{\epsilon}},\quad X_2=X_0\left(\frac{k_1}{k_2}\right)^{\frac{1}{2}}\frac{1}{\sqrt{\epsilon}}.$$

Therefore $\qquad X_1/X_2=k_1/k_2,$

or the force at the positive plate is to that at the negative plate as the velocity of the positive ion is to that of the negative ion. Thus the force at the negative plate is greater than that at the positive. The falls of potential V_1, V_2 at the two layers when $1/\epsilon$ is large can be shown to be given by the equations

$$V_1=8\pi^2\left(\frac{\epsilon}{q\alpha}\right)^{\frac{3}{2}}k_1\left(\frac{k_1}{k_2}\right)^{\frac{1}{2}}i^2,$$

$$V_2=8\pi^2\left(\frac{\epsilon}{q\alpha}\right)^{\frac{3}{2}}k_2\left(\frac{k_2}{k_1}\right)^{\frac{1}{2}}i^2,$$

hence $\qquad V_1/V_2=k_1^2/k_2^2,$

so that the potential falls at the electrodes are proportional to the squares of the velocities of the ions. The change in potential across the layers is proportional to the square of the current, while the potential change between the layers is proportional to the current, the total potential difference between the plates is the sum of these changes, hence the relation between V and i will be of the form

$$V=Ai+Bi^2.$$

Mie (*Ann. der. Phys.*, 1904, 13, p. 857) has by the method of successive approximations obtained solutions of equation (8) (i.) when the current is only a small fraction of the saturation current, (ii.) when the current is nearly saturated. The results of his investigations are represented in fig. 8, which represents the distribution of electric force along the path of the current for various values of the current expressed as fractions of the saturation current. It will be seen that until the current amounts to about one-fifth of the maximum current, the type of solution is the one just indicated, *i.e.*, the electric force is constant except in the neighbourhood of the electrodes when it increases rapidly.

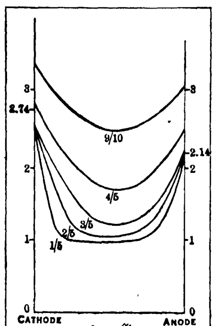

FIG. 8

Though we are unable to obtain a general solution of the equation (8), there are some very important special cases in which that equation can be solved without difficulty. We shall consider two of these, the first being that when the current is saturated. In this case there is no loss of ions by recombination, so that using the same notation as before we have

$$\frac{d}{dx}(n_1k_1X)=q,$$

$$\frac{d}{dx}(n_2k_2X)=-q.$$

The solutions of which if q is constant are

$$n_1k_1X=qx,$$

$$n_2k_2X=I/e-qx=q(l'-x),$$

if l is the distance between the plates, and $x=0$ at the positive electrode. Since

$$dX/dx=4\pi(n_1-n_2)e,$$

we get

$$\frac{1}{8\pi}\frac{dX^2}{d^2x}=qx\left\{\frac{1}{k_1}+\frac{1}{k_2}\right\}-q\frac{l}{k_2},$$

or

$$\frac{X^2}{8\pi}=q\frac{x^2}{2}\left(\frac{1}{k_1}+\frac{1}{k_2}\right)-q\frac{lx}{k_2}+C,$$

where C is a quantity to be determined by the condition that $\int_0^l Xdx=V$, where V is the given potential difference between the plates. When the force is a minimum $dX/dx=0$, hence at this point

$$x=\frac{lk_1}{k_1+k_2},\ l-x=\frac{lk_2}{k_1+k_2}.$$

Hence the ratio of the distances of this point from the positive and negative plates respectively is equal to the ratio of the velocities of the positive and negative ions.

The other case we shall consider is the very important one in which the velocity of the negative ion is exceedingly large compared with the positive; this is the case in flames where, as Gold (*Proc. Roy. Soc.* 97, p. 43) has shown, the velocity of the negative ion is many thousand times the velocity of the positive; it is also very probably the case in all gases when the pressure is low. We may get the solution of this case either by putting $k_1/k_2=0$ in equation (8). In this case the electric force except close to the cathode is constant and given by the equation

$$X_0=\sqrt{\left(\frac{\alpha}{q}\frac{i}{\epsilon k_2}\right)}.$$

The force at the cathode is approximately

$$2\left(\frac{\pi e}{qk_1}\right)^{\frac{1}{2}}\frac{i}{e}.$$

The thickness of the space within which the force falls from this value to X_0 is

$$\frac{i}{qe}$$

and the fall of potential in crossing this space is

$$\left(\frac{\pi e}{q^3k_1}\right)^{\frac{1}{2}}\frac{i^2}{e^2}$$

if l is the distance between the electrodes, V the total fall of potential is given by the equation

$$V=\left(\frac{\pi e}{q^3k_1}\right)^{\frac{1}{2}}\frac{i^2}{e^2}+\left(l-\frac{i}{qe}\right)\left(\frac{\alpha}{qk_2^2}\right)^{\frac{1}{2}}\frac{i}{e}.$$

If the cathode itself emits electrons, these will help to carry the current, and the thickness of the region of large force next the cathode will be $(i-i^0)$ where i^0 is the current carried by the electrons coming from the cathode. This will make the fall of potential at the cathode proportional to $i\,(i-i^0)$ instead of to i^2. The fall of potential at the cathode is proportional to the square of the current, while the fall in the rest of the circuit is directly proportional to the current. In the case of flames or hot gases, the fall of potential at the cathode is much greater than that in the rest of the circuit, so that in such cases the current through the gas varies nearly as the square root of the potential difference. The equation we have just obtained is of the form

$$V=Ai+Bi^2,$$

and H. A. Wilson has shown that a relation of this form represents the results of his experiments on the conduction of electricity through flames.

The expression for the fall of potential at the cathode is inversely proportional to $q^{3/2}$, q being the number of ions produced per cubic centimetre per second close to the cathode; thus any increase in the ionization at the cathode will diminish the potential fall at the cathode, and as practically the whole potential difference between the electrodes occurs at the cathode, a diminution in the potential fall there will be much more important than a diminution in the electric force in the uniform part of the discharge, where the force is comparatively insignificant. This consideration explains a very striking phenomenon discovered many years ago by Hittorf, who found that if he put a wire carrying a bead of a volatile salt into the flame, it produced little effect upon the current, unless it were placed close to the cathode where it gave rise to an enormous increase in the current, sometimes increasing the current more than a hundredfold. The introduction of the salt increases very largely the number of ions produced, so that q is much greater for a salted flame than for a plain one. Thus Hittorf's result coincides with the conclusions we have drawn from the theory of this class of conduction.

The fall of potential at the cathode is proportional to $i-i_0$, where i_0 is the stream of negative electricity which comes from the cathode itself, thus as i_0 increases the fall of potential at the cathode diminishes and the current sent by a given potential difference through the gas increases. Now all metals give out negative particles when heated, at a rate which increases very rapidly with the temperature, but at the same temperature some metals give out more than others. If the cathode is made of a metal which emits large quantities of negative particles, $(i-i_0)$ will for a given value of i be smaller than if the metal only emitted a small number of particles; thus the cathode fall will be smaller for the metal with the greater emissivity, and the relation between the potential difference and the current will be different in the two cases. These considerations are confirmed by experience, for it has been found that the current between electrodes immersed in a flame depends to a great extent upon the metal of which the electrodes are made. Thus Pettinelli (*Acc. dei Lincei* [5], v. p. 118) found that, *ceteris paribus*, the current between two carbon electrodes was about 500 times that between two iron ones. If one electrode was carbon and the other iron, the current when the carbon was cathode and the iron anode was more than 100 times the current when the electrodes were reversed. The emission of negative particles by some metallic oxides, notably those of calcium and barium, has been shown by Wehnelt (*Ann. der Phys.* 11, p. 425) to be far greater than that of any known metal, and the increase of current produced by coating the cathodes with these oxides is exceedingly large; in some cases investigated by Tufts and Stark (*Physik. Zeits.*, 1908, 5, p. 248) the current was increased many thousand times by coating the cathode with lime. No appreciable effect is produced by putting lime on the anode.

Conduction When All the Ions Are of One Sign. *The Space Charge Effect.*—There are many important cases in which the ions producing the current come from one electrode or from a thin layer of gas close to the electrode, no ionization occurring in the body of the gas or at the other electrode. Among such cases may be mentioned those where one of the electrodes is raised to incandescence while the other is cold, or when the negative electrode is exposed to ultra-violet light. In such cases if the electrode at which the ionization occurs is the positive electrode, all the ions will be positively charged, while if it is the negative electrode the ions will all be charged negatively. The theory of this case is exceedingly simple. Suppose the electrodes are parallel planes at right angles to the axis of x; let X be the electric force at a distance x from the electrode where the ionization occurs, n the number of ions (all of which are of one sign) at this place per cubic centimetre, k the velocity of the ion under unit electric force, e the charge on an ion, and i the current per unit area of the electrode. Then we have $\frac{dX}{dx}=4\pi ne$, and if u is the velocity of the ion $neu=i$. But $u=kX$, hence we have $\frac{kX}{4\pi}\frac{dX}{dx}=i$, and since the right hand side of this equation does not depend upon x, we get $kX^2/8\pi=ix+C$, where C is a constant to be determined. If l is the distance between the plates, and V the potential difference between them,

$$V=\int_0^l Xdx=\frac{1}{i}\sqrt{\frac{8\pi}{k}}\left[(il+C)^{\frac{3}{2}}-C^{\frac{3}{2}}\right]$$

We shall show that when the current is far below the saturation value, C is very small compared with il, so that the preceding equation becomes

$$V^2 = 8\pi l^3 i/k. \tag{1}$$

To show that for small currents C is small compared with il, consider the case when the ionization is confined to a thin layer, thickness d close to the electrode: in that layer let n_0 be the value of n, then we have $q = \alpha n_0^2 + i/ed$. If X_0 be the value of X when $x = 0$, $kX_0 n_0 e = i$, and

$$C = \frac{kX_0^2}{8\pi} = \frac{i^2}{n_0^2 ke \cdot 8\pi} = \frac{\alpha}{8\pi ke^2} \cdot \frac{i^2}{q - i/ed}. \tag{2}$$

Since $\alpha/8\pi ke$ is, as we have seen, less than unity, C will be small compared with il, if $i/(eq + i/d)$ is small compared with l. If I_0 is the saturation current, $q = I_0/ed$, so that the former expression $= id/(I_0 - i)$, if i is small compared with I_0, this expression is small compared with d, and therefore *a fortiori* compared with l, so that we are justified in this case in using equation (1).

From equation (1) we see that the current increases as the square of the potential difference. Here an increase in the potential difference produces a much greater percentage increase than in conduction through metals, where the current is proportional to the potential difference. When the ionization is distributed through the gas, we have seen that the current is approximately proportional to the square root of the potential, and so increases more slowly with the potential difference than currents through metals. From equation (1) the current is inversely proportional to the cube of the distance between the electrodes, so that it falls off with great rapidity as this distance is increased. We may note that for a given potential difference the expression for the current does not involve q, the rate of production of the ions at the electrode; in other words, if we vary the ionization the current will not begin to be affected by the strength of the ionization until this falls so low that the current is a considerable fraction of the saturation current. For the same potential difference the current is proportional to k, the velocity under unit electric force of the ion which carries the current. As the velocity of the negative ion is greater than that of the positive, the current when the ionization is confined to the neighbourhood of one of the electrodes will be greater when that electrode is made cathode than when it is anode. Thus the current will appear to pass more easily in one direction than in the opposite.

Since the ions which carry the current have to travel all the way from one electrode to the other, any obstacle which is impervious to these ions will, if placed between the electrodes, stop the current to the electrode where there is no ionization. A plate of metal will be as effectual as one made of a non-conductor, and thus we get the remarkable result that by interposing a plate of an excellent conductor like copper or silver between the electrode we can entirely stop the current. This experiment can easily be tried by using a hot plate as the electrode at which the ionization takes place: then if the other electrode is cold the current which passes when the hot plate is cathode can be entirely stopped by interposing a cold metal plate between the electrodes.

A very interesting case of the space charge effect is when, as above, the ions are produced close to one electrode or are emitted by it and the pressure of the gas is so low that the motion of the ions is not affected by the presence of the gas. This includes the very important case where currents are carried through a vacuum by the electrons emitted from an incandescent electrode.

If V be the potential difference between a point P in the gas and this electrode, n the number of ions per cc. at P m the mass and e the charge on the ion, x the distance of P from the electrode. Then

$$\frac{d^2V}{dx^2} = 4\pi ne \text{ - - - -} \tag{3}$$

If V is the velocity of the ion at P, then if it starts from rest at the electrode

$$\tfrac{1}{2}mv^2 = Ve \text{ - - - -} \tag{4}$$

and if l is the current through unit area

$$l = nev \tag{5}$$

from these equations we get

$$\sqrt{\left(V \cdot \frac{d^2V}{dx^2}\right)} = 4\pi l\,(m/ze)^{\frac{1}{2}}. \tag{6}$$

A complete solution of this equation can be obtained without difficulty; the expressions for this solution are, however, somewhat complicated, and we shall confine ourselves to the special case when the current passing is small compared with the saturation current, in this case dV/dx vanishes at the electrode and the solution of (6) is

$$V = \{9i(m/u)^{\frac{1}{2}}\}^{\frac{2}{3}} \cdot x^{\frac{4}{3}} \tag{7}$$

or i the current sent by a potential difference V, when l is the distance between the electrode is given by

$$l = \frac{1}{9}\sqrt{\frac{2e}{m}} \cdot \frac{V^{3/2}}{l^2} \tag{8}$$

Thus the current produced by a given potential difference is independent of the rate at which the electrons are emitted from the electrode; this is, however, only true when the current is far from saturation.

We see from equation (3) that $\frac{d^2V}{dx^2}$ extend, therefore n are infinite when $x = o$, so that there is a great accumulation of ions close to this electrode.

The "space charge effect" has been the subject of most important investigations by Langmuir, to whom its development is mainly due.

Methods of Counting the Number of Ions.—The detection of the ions and the estimation of their number in a given volume is much facilitated by the property they possess of promoting the condensation of water-drops in dust-free air supersaturated with water vapour. If such air contains no ions, then it requires about an eightfold supersaturation before any water-drops are formed; if, however, ions are present C. T. R. Wilson (*Phil. Trans.*, 189, p. 265) has shown that a sixfold supersaturation is sufficient to cause the water vapour to condense round the ions and to fall down as raindrops. The absence of the drops when no ions are present is due to the curvature of the drop combined with the surface tension causing, as Lord Kelvin showed, the evaporation from a small drop to be exceedingly rapid, so that even if a drop of water were formed the evaporation when it was small would be so great that it would rapidly evaporate and disappear. It has been shown, however (J. J. Thomson, *Application of Dynamics to Physics and Chemistry*, p. 164; *Conduction of Electricity through Gases*, 2nd ed. p. 179), that if a drop of water is charged with electricity the effect of the charge is to diminish the evaporation; if the drop is below a certain size the effect of the charge in promoting condensation more than counterbalances the effect of the surface tension in promoting evaporation. Thus the electric charge protects the drop in the most critical period of its growth.

The effect is easily shown experimentally by taking a bulb connected with a piston arranged so as to move with great rapidity. When the piston moves so as to increase the volume of the air contained in the bulb the air is cooled by expansion, and if it was saturated with water vapour before it is supersaturated after the expansion. By altering the throw of the piston the amount of supersaturation can be adjusted within very wide limits. Let it be adjusted so that the expansion produces about a sixfold supersaturation; then if the gas is not exposed to any ionizing agents very few drops (and these probably due to the small amount of ionization which we have seen is always present in gases) are formed. If, however, the bulb is exposed to strong Röntgen rays expansion produces a dense cloud which gradually falls down and disappears. If the gas in the bulb at the time of its exposure to the Röntgen rays is subject to a strong electric field hardly any cloud is formed when the gas is suddenly expanded. The electric field removes the charged ions from the gas as soon as they

are formed so that the number of ions present is greatly reduced. This experiment furnishes a very direct proof that the drops of water which form the cloud are only formed round the ions.

This method gives us an exceedingly delicate test for the presence of ions, for there is no difficulty in detecting ten or so raindrops per cubic centimetre; we are thus able to detect the presence of this number of ions. This result illustrates the enormous difference between the delicacy of the methods of detecting ions and those for detecting uncharged molecules; we have seen that we can easily detect ten ions per cubic centimetre, but there is no known method, spectroscopic or chemical, which would enable us to detect a billion (10^{12}) times this number of uncharged molecules. The formation of the water-drops round the charged ions gives us a means of counting the number of ions present in a cubic centimetre of gas; we cool the gas by sudden expansion until the supersaturation produced by the cooling is sufficient to cause a cloud to be formed round the ions, and the problem of finding the number of ions per cubic centimetre of gas is thus reduced to that of finding the number of drops per cubic centimetre in the cloud. Unless the drops are very few and far between we cannot do this by direct counting; we can, however, arrive at the result in the following way. From the amount of expansion of the gas we can calculate the lowering produced in its temperature and hence the total quantity of water precipitated. The water is precipitated as drops, and if all the drops are the same size the number per cubic centimetre will be equal to the volume of water deposited per cubic centimetre, divided by the volume of one of the drops. Hence we can calculate the number of drops if we know their size, and this can be determined by measuring the velocity with which they fall under gravity through the air.

Stokes showed that the force required to drive a drop of water with a velocity v through a continuous fluid is equal to $6\pi\mu av$ where a is the radius of the drop and μ the viscosity of the fluid. Cunningham (*Proc. Roy. Soc.*, F3, A. p. 357) showed that this expression requires modification when the drop moves through a gas in which the mean free path of the molecules is comparable with the radius of the drop. He shows that the factor $6\pi\mu a$ must be replaced by $6\pi\mu a\left(1+1\cdot63\frac{l}{a}\right)^{-1}$ where l is the mean free path of the molecules. Since l varies inversely as the pressure, p, of the gas the factor is of the form $6\pi\mu a\left(1+\frac{B}{pa}\right)^{-1}$ where B is a constant. Milliken, assuming an expression of this form, determined the value of B by experiment. When the drop falls under gravity the force is $\frac{4}{3}\pi g a^3(\rho-\sigma)$ when ρ is the density of the drop and σ that of the gas. Since this is equal to V multiplied by a known function of a, if we measure V we can deduce the value of a.

Charge on Ion.—By this method we can determine the number of ions per unit volume of an ionized gas. Knowing this number we can proceed to determine the charge on an ion. To do this let us apply an electric force so as to send a current of electricity through the gas, taking care that the current is only a small fraction of the saturating current. Then if u is the sum of the velocities of the positive and negative ions produced in the electric field applied to the gas, the current through unit area of the gas is neu, where n is the number of positive or negative ions per cubic centimetre, and e the charge on an ion. We can easily measure the current through the gas and thus determine neu; we can determine n by the method just described, and u, the velocity of the ions under the given electric field, is known from the experiments of Zeleny and others. Thus since the product neu, and two of the factors n, u are known, we can determine the other factor e, the charge on the ion. (This method was used by J. J. Thomson, and details of the method will be found in *Phil. Mag.* [5], 46, p. 528; [5], 48, p. 547; [6], 5, p. 346). The result of these measurements shows that the charge on the ion is the same whether the ionization is by Röntgen rays or by the influence of ultra-violet light on a metal plate. It is the same whether the gas ionized is hydrogen, air or carbonic acid, and thus is presumably independent of the nature of the gas. The value of e found by this method was $3\cdot4\times10^{-10}$ electrostatic units.

H. A. Wilson (*Phil. Mag.* [6], 5, p. 429) used another method. Drops of water, as we have seen, condense more easily on negative than on positive ions. It is possible, therefore, to adjust the expansion so that a cloud is formed on the negative but not on the positive ions. Wilson arranged the experiments so that such a cloud was formed between two horizontal plates which could be maintained at different potentials. The charged drops between the plates were acted upon by a uniform vertical force which affected their rate of fall. Let X be the vertical electric force, e the charge on the drop, v_1 the rate of fall of the drop when this force acts, and v the rate of fall due to gravity alone. Then since the rate of fall is proportionate to the force on the drop, if a is the radius of the drop, and ρ its density, then

$$\frac{Xe+\frac{4}{3}\pi\rho g a^3}{\frac{4}{3}\pi\rho g a^3}=\frac{v_1}{v},$$

or

$$Xe=\tfrac{4}{3}\pi\rho g a^3(v_1-v)/v.$$

But

$$v=\tfrac{2}{9}ga^2\rho/\mu,\ \text{approximately},$$

so that

$$Xe=\sqrt{2}\cdot9\pi\sqrt{\frac{\mu^3}{g\rho}}\cdot\frac{v^{\frac{1}{2}}(v_1-v)}{v}.$$

Thus if X, v, v_1 are known e can be determined. Wilson by this method found that e was $3\cdot1\times10^{-10}$ electrostatic units. A few of the ions carried charges $2e$ or $3e$.

Townsend has used the following method to compare the charge carried by a gaseous ion with that carried by an atom of hydrogen in the electrolysis of solution. We have

$$u/\mathrm{D}=\mathrm{N}e/\pi,$$

where D is the coefficient of diffusion of the ions through the gas, u the velocity of the ion in the same gas when acted on by unit electric force, N the number of molecules in a cubic centimetre of the gas when the pressure is π dynes per square centimetre, and e the charge in electrostatic units. This relation is obtained on the hypothesis that N ions in a cubic centimetre produce the same pressure as N uncharged molecules.

We know the value of D from Townsend's experiments and the values of u from those of Żeleny. We get the following values for $\mathrm{N}e\times10^{-10}$:—

Gas	Moist gas		Dry gas	
	Positive ions	Negative ions	Positive ions	Negative ions
Air	1·28	1·29	1·46	1·31
Oxygen	1·34	1·27	1·63	1·36
Carbonic acid	1·01	·87	·99	·93
Hydrogen	1·24	1·18	1·63	1·25
Mean	1·22	1·15	1·43	1·21

Since 1·22 cubic centimetres of hydrogen at the temperature 15° C and pressure 760 mm. of mercury are liberated by the passage through acidulated water of one electromagnetic unit of electricity or 3×10^{10} electrostatic units, and since in one cubic centimetre of the gas there are 2·46 N atoms of hydrogen, we have, if E is the charge in electrostatic units, on the atom of hydrogen in the electrolysis of solutions

$$2\cdot46\mathrm{NE}=3\times10^{10},$$

or

$$2\cdot46\mathrm{NE}=3\times10^{10}.$$

The mean of the values of Ne in the preceding table is $1\cdot24\times10^{10}$. Hence we may conclude that the charge of electricity carried by a gaseous ion is equal to the charge carried by the hydrogen atom in the electrolysis of solutions. The values of Ne for the different gases differ more than we should have expected from the probable accuracy of the determination of D and the velocity of the ions: Townsend (*Proc. Roy. Soc.* 80, p. 207) has shown that when the ionization is produced by Röntgen rays some of the positive ions carry a double charge and that this accounts for the values of Ne being greater for the positive than for the negative ions. Since we know the value of e, viz., $4\cdot77\times10^{-10}$, and, also Ne, $=1\cdot24\times10^{10}$, we find N the number of molecules in a cubic

centimetre of gas at standard temperature and pressure to be equal to 2.6×10^{10}. This method of obtaining N is the only one which does not involve any assumption as to the shape of the molecules and the forces acting between them.

Another method of determining the charge carried by an ion has been employed by Rutherford (*Proc. Roy. Soc.* 81, pp. 141, 162), in which the positively electrified particles emitted by radium are made use of. The method consists of: (1) Counting the number of α particles emitted by a given quantity of radium in a known time. (2) Measuring the electric charge emitted by this quantity in the same time. To count the number of the α particles the radium was so arranged that it shot into an ionization chamber a small number of α particles per minute; the interval between the emission of individual particles was several seconds. When an α particle passed into the vessel it ionized the gas inside and so greatly increased its conductivity; thus, if the gas were kept exposed to an electric field, the current through the gas would suddenly increase when an α particle passed into the vessel. Although each α particle produces about 30 thousand ions, this is hardly large enough to produce the conductivity appreciable without the use of very delicate apparatus; to increase the conductivity Rutherford took advantage of the fact that negative ions, when exposed to a strong electric field, produce other ions by collision against the molecules of the gas through which they are moving. By suitably choosing the electric field and the pressure in the ionization chamber, the 30,000 ions produced by each α particle can be multiplied to such an extent that an appreciable current passes through the ionization chamber on the arrival of each α particle. An electrometer placed in series with this vessel will show by its deflection when an α particle enters the chamber, and by counting the number of deflections per minute we can determine the number of α particles given out by the radium in that time. Another method of counting this number is to let the particles fall on a phosphorescent screen, and count the number of scintillations on the screen in a certain time. Rutherford has shown that these two methods give concordant results.

The charge of positive electricity given out by the radium was measured by catching the α particles in a Faraday cylinder placed in a very highly exhausted vessel, and measuring the charge per minute received by this cylinder. In this way Rutherford showed that the charge on the α particle was 9.4×10^{-10} electrostatic units. Now e/m for the α particle $=5\times10^{3}$, and there is evidence that the α particle is a charged atom of helium; since the atomic weight of helium is 4 and e/m for hydrogen is 10^{4}, it follows that the charge on the helium atom is twice that on the hydrogen, so that the charge on the hydrogen atom is 4.7×10^{-10} electrostatic units.

Calculation of the Mass of the Ions at Low Pressures.—Although at ordinary pressures the ion seems to have a very complex structure and to be the aggregate of many molecules, yet we have evidence that at very low pressures the structure of the ion, and especially of the negative one, becomes very much simpler. This evidence is afforded by determination of the mass of the atom. We can measure the ratio of the mass of an ion to the charge on the ion by observing the deflections produced by magnetic and electric forces on a moving ion. If an ion carrying a charge e is moving with a velocity v, at a point where the magnetic force is H, a mechanical force acts on the ion, whose direction is at right angles both to the direction of motion of the ion and to the magnetic force, and whose magnitude is $ev\mathrm{H}\sin\theta$ where θ is the angle between v and H. Suppose then that we have an ion moving through a gas whose pressure is so low that the free path of the ion is long compared with the distance through which it moves whilst we are experimenting upon it; in this case the motion of the ion will be free, and will not be affected by the presence of the gas.

Since the force is always at right angles to the direction of motion of the ion, the speed of the ion will not be altered by the action of this force; and if the ion is projected with a velocity v in a direction at right angles to the magnetic force, and if the magnetic force is constant in magnitude and direction, the ion will describe a curve in a plane at right angles to the magnetic force. If ρ is the radius of curvature of this curve, m the mass of the ion, mv^2/ρ must equal the normal force acting on the ion, *i.e.* it must be equal to Hev, or $\rho=mv/\mathrm{H}e$. Thus the radius of curvature is constant; the path is therefore a circle, and if we can measure the radius of this circle we know the value of $mv/\mathrm{H}e$. In the case of the rapidly moving negative ions projected from the cathode in a highly exhausted tube, which are known as *cathode rays*, the path of the ions can be readily determined since they make many substances luminous when they impinge against them. Thus by putting a screen of such a substance in the path of the rays the shape of the path will be determined. Let us now suppose that the ion is acted upon by a vertical electric force X and is free from magnetic force, if it be projected with a horizontal velocity v, the vertical deflection y after a time t is $\frac{1}{2}\times et^2/m$, or if l is the horizontal distance travelled over by the ions in this time we have, since $l=vt$,

$$y=\tfrac{1}{2}\,\frac{Xe}{m}\,\frac{l^2}{v^2}.$$

Thus if we measure y and l we can deduce e/mv^2. From the effect of the magnetic force we know e/mv. Combining these results we can find both e/m and v.

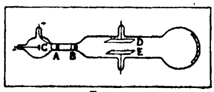

FIG. 9

The method by which this determination is carried out in practice is illustrated in fig. 9. The cathode rays start from the electrode C in a highly exhausted tube, pass through two small holes in the plugs A and B, the holes being in the same horizontal line. Thus a pencil of rays emerging from B is horizontal and produces a bright spot at the far end of the tube. In the course of their journey to the end of the tube they pass between the horizontal plates E and D, by connecting these plates with an electric battery a vertical electric field is produced between E and D and the phosphorescent spot is deflected. By measuring this deflection we determine e/mv^2. The tube is now placed in a uniform magnetic field, the lines of magnetic force being horizontal and at right angles to the plane of the paper. The magnetic force makes the rays describe a circle in the plane of the paper, and by measuring the vertical deflection of the phosphorescent patch at the end of the tube we can determine the radius of this circle, and hence the value of e/mv. From the two observations the value of e/m and v can be calculated.

Another method of finding e/m for the negative ion which is applicable in many cases, to which the preceding one is not suitable, is as follows: Let us suppose that the ion starts from rest and moves in a field where the electric and magnetic forces are both uniform, the electric force X being parallel to the axis of x, and the magnetic force Z parallel to the axis of z; then if x, y, are the coordinates of the ion at the time t, the equations of motion of the ion are—

$$m\frac{d^2x}{dt^2}=Xe-He\frac{dy}{dt},$$

$$m\frac{d^2y}{dt^2}=He\frac{dx}{dt}.$$

The solution of these equations, if x, y, dx/dt, dy/dt all vanish when $t=0$, is

$$x=\frac{Xm}{eH^2}\left\{1-\cos\left(\frac{e}{m}Ht\right)\right\}$$

$$y=\frac{Xm}{eH^2}\left\{\frac{e}{m}Ht-\sin\left(\frac{e}{m}Ht\right)\right\}.$$

These equations show that the path of the ion is a cycloid, the generating circle of which has a diameter equal to $2\mathrm{X}m/e\mathrm{H}^2$, and rolls on the line $x=0$.

Suppose now that we have a number of ions starting from the plane $x=0$, and moving towards the plane $x=a$. The particles starting from $x=0$ describe cycloids, and the greatest distance they can get from the plane is equal to the diameter of the generating circle of the cycloid, *i.e.* to $2\mathrm{X}m/e\mathrm{H}^2$. (After reaching this distance they begin to approach the plane.) Hence if a is less than

the diameter of the generating circle, all the particles starting from $x=0$ will reach the plane $x=a$, if this is unlimited in extent; while if a is greater than the diameter of the generating circle none of the particles which start from $x=0$ will reach the plane $x=a$. Thus, if $x=0$ is a plane illuminated by ultra-violet light, and consequently the seat of a supply of negative ions, and $x=a$ a plane connected with an electrometer, then if a definite electric intensity is established between the planes, *i.e.*, if X be fixed, so that the rate of emission of negative ions from the illuminated plate is given, and if a is less than $2Xm/eH^2$, all the ions which start from $x=0$ will reach $x=a$. That is, the rate at which this plane receives an electric charge will be the same whether there is a magnetic field between the plate or not, but if a *is* greater than $2Xm/eH^2$, then no particle which starts from the plate $x=0$ will reach the plate $x=a$, and this plate will receive no charge. Thus the supply of electricity to the plate has been entirely stopped by the magnetic field. Thus, on this theory, if the distance between the plates is less than a certain value, the magnetic force should produce no effect on the rate at which the electrometer plate receives a charge, while if the distance is greater than this value the magnetic force would completely stop the supply of electricity to the plate. The actual phenomena are not so abrupt as this theory indicates. We find that when the plates are very near together the magnetic force produces a very slight effect, and thus an *increase* in the rate of charging of the plate. On increasing the distance we come to a stage where the magnetic force produces a great diminution in the rate of charging. It does not, however, stop it abruptly, there being a considerable range of distance, in which the magnetic force diminishes but does not destroy the current. At still greater distances the current to the plate under the magnetic force is quite inappreciable compared with that when there is no magnetic force. We should get this gradual instead of abrupt decay of the current if some of the particles, instead of all starting from rest, started with a finite velocity; in that case the first particles stopped would be those which started from rest. This would be when $a=2Xm/eH^2$. Thus if we measure the value of a when the magnetic force first begins to affect the leak to the electrometer we determine $2Xm/eH^2$, and as we can easily measure X and H, we can deduce the value of m/e.

By these methods J. J. Thomson determined the value of e/m for the negative ions produced when ultra-violet light falls on a metal plate, as well as for the negative ions produced by an incandescent carbon filament in an atmosphere of hydrogen (*Phil. Mag.* [5], 48, p. 547) as well as for the cathode rays. It was found that the value of e/m for the negative ions was the same in all these cases, and that it was a constant quantity independent of the nature of the gas from which the ions are produced and the means used to produce them. It was found, too, that this value was more than a thousand times the value of e/M, where e is the charge carried by an atom of hydrogen in the electrolysis of solutions, and M the mass of an atom of hydrogen. We have seen that this charge is the same as that carried by the negative ion in gases; thus since e/m is more than a thousand times e/M, it follows that M must be more than a thousand times m. Thus the mass of the negative ion is exceedingly small compared with the mass of the atom of hydrogen, the smallest mass recognized in chemistry. The production of negative ions thus involves the splitting up of the atom, as from a collection of atoms something is detached whose mass is less than that of a single atom. It is important to notice in connection with this subject that an entirely different line of argument, based on the Zeeman effect (*q.v.*), leads to the recognition of negatively electrified particles for which e/m is of the same order as that deduced from the consideration of purely electrical phenomena. These small negatively electrified particles are called electrons. The latest determinations of e/m for electrons available are given in the table in the next column.

It follows from electrical theory that when the electrons are moving with a velocity comparable with that of light their masses increase rapidly with their velocity. This effect has been detected by Kauffmann (*Gött. Nach.*, Nov. 8, 1901), who used the electrons shot out from radium, some of which move with velocities only a few per cent less than that of light. Other experiments on this point have been made by Bucherer (*Ann. der Phys.* 28, p. 513).

Values of e/m

Source of ions	Observer	Date	Method of determination	Value of e/m
Radium	Kaufmann	1901–02	Magnetic and electrostatic deflection	$1{\cdot}77\times10^7$
X-rays	Bestelmeyer	1907	Magnetic and electrostatic deflection (crossed fields)	$1{\cdot}72\times10^7$
Incandescent oxide	Bestelmeyer	1911	Magnetic deflection and potential difference	$1{\cdot}767\times10^7$
Incandescent oxide	Classen	1907	Magnetic deflection and potential difference	$1{\cdot}775\times10^7$
Ultra-violet light	Alberti	1912	Magnetic deflection and potential difference	$1{\cdot}756\times10^7$ $1{\cdot}766\times10^7$
Radium	Bucherer	1909	Magnetic and electrostatic deflection (crossed fields)	$1{\cdot}763\times10^7$
Radium	Woltz	1909	Magnetic and electrostatic deflection (crossed fields)	$1{\cdot}77\times10^7$
Radium	Neumann	1914	Magnetic and electrostatic deflection (crossed fields)	$1{\cdot}765\times10^7$
..	Fortrat	1912	Zeeman effect	$1{\cdot}763\times10^7$
..	Paschen	1916	Bohr's theory	$1{\cdot}765\times10^7$

Conductivity Produced by Ultra-violet Light. (*See* PHOTOELECTRICITY.)—The electrical effects produced by light have had such great influence on our views as to the nature of light and electricity that it is desirable to consider them in some detail. The discovery by Hertz (*Wied. Ann.* 31, p. 983), in 1887, that the incidence of ultra-violet light on a spark gap facilitates the passage of a spark, led to a series of investigations by Hallwachs, Hoor, Righi and Stoletow, on the effect of ultra-violet light on electrified bodies. These researches have shown that a freshly cleaned metal surface, charged with negative electricity, rapidly loses its charge, however small, when exposed to ultra-violet light, and that if the surface is insulated and without charge initially, it acquires a positive charge under the influence of the light. The magnitude of this positive charge may be very much increased by directing a blast of air on the plate. This, as Zeleny (*Phil. Mag.* [5], 45, p. 272) showed, has the effect of blowing from the neighbourhood of the plate negatively electrified gas, which has similar properties to the charged gas obtained by the separation of ions from a gas exposed to Röntgen rays or uranium radiation. If the metal plate is positively electrified, there is no loss of electrification caused by ultra-violet light.

This has been questioned, but very careful examination of the question by Elster and Geitel (*Wied. Ann.* 57, p. 24) showed that the apparent exceptions were due to the accidental exposure to reflected ultra-violet light of metal surfaces in the neighbourhood of the plate negatively electrified by induction, so that the apparent loss of charge was due to negative electricity coming up to the plate, and not to positive electricity going away from it. The ultra-violet light may be obtained from an arc-lamp, the effectiveness of which is increased if one of the terminals is made of zinc or aluminium, the light from these substances being very rich in ultra-violet rays; it may also be got very conveniently by sparking with an induction coil between zinc or cadmium terminals. Sunlight is not rich in ultra-violet light, and does not produce anything like so great an effect as the arc-light. Elster and Geitel, who have investigated with great success the effects of light on electrified bodies, have shown that the more electropositive metals lose negative charges when exposed to ordinary

light, and do not need the presence of the ultra-violet rays. Thus they found that amalgams of sodium or potassium enclosed in a glass vessel lose a negative charge when exposed to daylight, though the glass stops the small amount of ultra-violet light left in sunlight after its passage through the atmosphere. If sodium or potassium be employed, or, what is more convenient, the mercury-like liquid obtained by mixing sodium and potassium in the proportion of their combining weights, they found that negative electricity was discharged by an ordinary petroleum lamp. If the still more electro-positive metal rubidium is used, the discharge can be produced by the light from a glass rod just heated to redness; but there is no discharge till the glass is luminous.

Elster and Geitel arrange the metals in the following order for the facility with which negative electrification is discharged by light: rubidium, potassium, alloy of sodium and potassium, sodium, lithium, magnesium, thallium, zinc. With copper, platinum, lead, iron, cadmium, carbon and mercury the effects with ordinary light are too small to be appreciable. The order is the same as that in Volta's electro-chemical series. With ultra-violet light the different metals show much smaller differences in their power of discharging negative electricity than they do with ordinary light. Elster and Geitel found that the ratio of the photo-electric effects of two metals exposed to approximately monochromatic light depended upon the wave length of the light, different metals showing a maximum sensitiveness in different parts of the spectrum. This is shown by the following table for the alkaline metals. The numbers in the table are the rates of emission of negative electricity under similar circumstances. The rate of emission under the light from a petroleum lamp was taken as unity:—

	Blue	Yellow	Orange	Red
Rb	·16	·64	·33	·039
Na	·37	·36	·14	·009
K	·57	·07	·04	·002

The table shows that the absorption of light by the metal has great influence on the photo-electric effect, for while potassium is more sensitive in blue light than sodium, the strong absorption of yellow light by sodium makes it more than five times more sensitive to this light than potassium. Stoletow, at an early period, called attention to the connection between strong absorption and photo-electric effects. He showed that water, which does not absorb to any great extent either the ultra-violet or visible rays, does not show any photo-electric effect, while strongly coloured solutions, and especially solutions of fluorescent substances such as methyl green or methyl violet, do so to a very considerable extent; indeed, a solution of methyl green is more sensitive than zinc. Hallwachs (*Wied. Ann.* 37, p. 666) proved that in liquids showing photo-electric effects there is always strong absorption; we may, however, have absorption without these effects. Phosphorescent substances, such as calcium-sulphide, show this effect, as also do various specimens of fluor-spar. As phosphorescence and fluorescence are probably accompanied by a very intense absorption by the surface layers, the evidence is strong that to get the photo-electric effects we must have strong absorption of some kind of light, either visible or ultra-violet. The photo-electric effect seems to disappear immediately the light is cut off. Stoletow, who investigated this point, could not obtain any evidence of a finite interval between the incidence of the light and the attainment of the full photo-electric effect. Laurence and Bean (*Phys. Rev.* 29, p. 904, 1927) have shown that the time lap, if any, is less than 3×10^{-9} sec. both at starting and stopping the light.

If a conductor A is placed near a conductor B exposed to ultra-violet light, and if B is made the negative electrode and a difference of potential established between A and B, a current of electricity will flow between the conductors. The relation between the magnitude of the current and the difference of potential when A and B are parallel plates has been investigated by Stoletow (*Journal de physique*, 1890, 11, p. 469), von Schweidler (*Wien., Ber.*, 1899, 108, p. 273) and Varley (*Phil. Trans. A.*, 1904, 202, p. 439). The results of some of Varley's experiments are represented in the curves shown in fig. 10, in which the ordinates are the currents and the abscissae the potentials. It will be seen that when the pressure is exceedingly low the current is independent of the potential difference and is equal to the negative charge carried off in unit time by the electrons emitted from the surface exposed to the light. At higher pressures the current rises far above these values and increases rapidly with the potential difference. This is due to the electrons emitted by the illuminated surface acquiring under the electric field such high velocities that when they strike against the molecules of the gas through which they are passing they ionize them, producing fresh ions which can carry an additional current.

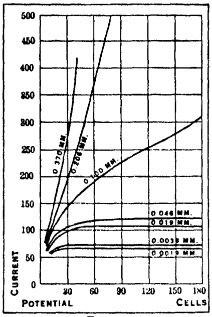

FIG. 10

The relation between the current and the potential difference in this case is in accordance with the results of the theory of ionization by collision. The electrons emitted from a body under the action of ultra-violet light start from the surface with a finite velocity. The velocity is not the same for all the electrons, nor indeed could we expect that it should be: for as Ladenburg has shown (*Ann. der Phys.*, 1903, 12, p. 558) the seat of their emission is not confined to the surface layer of the illuminated metal but extends to a layer of finite, though small, thickness. Thus the particles which start deep down will have to force their way through a layer of metal before they reach the surface, and in doing so will have their velocities retarded by an amount depending on the thickness of this layer. The variation in the velocity of the electrons is shown in the following table, due to Lenard (*Ann. der Phys.*, 1902, 8, p. 149).

	Carbon	Platinum	Aluminium
Electrons emitted with velocities between 12 and 8×10^7 cm. sec.	0·000	0·000	0·004
With velocities between 8 and 4×10^7 cm. sec.	0·049	0·155	0·151
With velocities between 4 and 0×10^7 cm. sec.	0·67	0·65	0·49
Electrons only emitted with the help of an external electric field	0·28	0·21	0·35
	1·00	1·00	1·00

If the illuminated surface is completely surrounded by an envelope of the same metal insulated from and completely shielded from the light, the emission of the negative electrons from the illuminated surface would go on until the potential difference V between this surface and the envelope became so great that the electrons with the greatest velocity lost their energy before reaching the envelope, *i.e.*, if m is the mass, e the charge on an electron, v the greatest velocity of projection, until $Ve=\frac{1}{2}mv^2$. The values found for V by different observers are not very consistent. Lenard found that V for aluminium was about 3 volts and for platinum 2. Millikan and Winchester (*Phil. Mag.*, July 1907) found for aluminium $V=\cdot738$. The apparatus used by them was so complex that the interpretation of their results is difficult.

An extremely interesting fact discovered by Lenard is that the velocity with which the electrons are emitted from the metal is independent of the intensity of the incident light. The number of electrons increases with the intensity, but the velocity of the individual electrons does not. It is worthy of notice that in other cases when negative electrons are emitted from metals, as for example when the metals are exposed to cathode rays, Canalstrahlen, or Röntgen rays, the velocity of the emitted electrons is independent of the intensity of the primary radiation which

excites them. The velocity is not, however, independent of the nature of the primary rays. Thus when light is used to produce the emission of electrons the velocity, as Ladenburg has shown, depends on the wave length of the light, increasing as the wave length diminishes. The velocity of electrons emitted under the action of cathode rays is greater than that of those ejected by light, while the incidence of Röntgen rays produces the emission of electrons moving much more rapidly than those in the cases already mentioned, and the harder the primary rays the greater is the velocity of the electrons.

The importance of the fact that the velocity and therefore the energy of the electrons emitted from the metal is independent of the intensity of the incident light can hardly be overestimated. It raises the most fundamental questions as to the nature of light and the constitution of the molecules. What is the source of the energy possessed by these electrons? Is it the light, or in the stores of internal energy possessed by the molecule? Let us follow the consequences of supposing that the energy comes from the light. Then, since the energy is independent of the intensity of the light, the electric forces which liberate the electrons must also be independent of that intensity. But this cannot be the case if, as is usually assumed in the electromagnetic theory, the wave front consists of a uniform distribution of electric force without structure, for in this case the magnitude of the electric force is proportional to the square root of the intensity.

On the emission theory of light a difficulty of this kind would not arise, for on that theory the energy in a luminiferous particle remains constant as the particle pursues its flight through space. Thus any process which a single particle is able to effect by virtue of its energy will be done just as well a thousand miles away from the source of light as at the source itself, though of course in a given space there will not be nearly so many particles to do this process far from the source as there are close in. Thus, if one of the particles when it struck against a piece of metal caused the ejection of an electron with a given velocity, the velocity of emission would not depend on the intensity of the light. There does not seem any reason for believing that the electromagnetic theory is inconsistent with the idea that on this theory, as on the emission theory, the energy in the light wave may, instead of being uniformly distributed through space, be concentrated in bundles which occupy only a small fraction of the volume traversed by the light, and that as the wave travels out the bundles get farther apart, the energy in each remaining undiminished.

Some such view of the structure of light seems to be required to account for the fact that when a plate of metal is struck by a wave of ultra-violet light, it would take years before the electrons emitted from the metal would equal in number the molecules on the surface of the metal plate, and yet on the ordinary theory of light each one of these is without interruption exposed to the action of the light. The fact discovered by E. Ladenburg (*Verh. d. deutsch. physik. Ges.* 9, p. 504) that the velocity with which the electrons are emitted depends on the wave length of the light suggests that the energy in each bundle depends upon the wave length and increases as the wave length diminishes.

This view was expressed in a very definite form by Planck, who proposed the theory that the energy of radiation is made up of units of finite size, the energy in a unit being equal to $h\nu$ where ν is the frequency of the light and h a constant, called Planck's constant, whose value in C.G.S. units is $6{\cdot}55\times10^{-27}$.

Though it was recognized from the first that the velocity of the electrons ejected by light increased with the frequency of the light it was some time before the technique of the experiments was sufficiently developed to determine whether the velocity or the energy of the electrons was a linear function of the frequency. Hughes (*Phil. Trans.* 212, p. 205, 1912) and Richardson and Compton (*Phil. Mag.* 24, p. 577, 1912) show that the second of these alternatives is the correct one and that the relation between v, the maximum velocity of the ejected electrons, and the frequency of the light

$$\tfrac{1}{2}mv^2 = k\nu - V_0e$$

where k is a constant and V_0 a potential characteristic of the substance emitting the electrons. Einstein suggested that k was equal to Planck's constant h and this was verified by Millikan in a very careful series of experiments (*Phys. Review*, 7, p. 355, 1916). So that

$$\tfrac{1}{2}mv^2 = h\nu - V_0e.$$

Thus no emission of electrons will take place unless ν is greater than ν_0 where $\nu_0 = V_0e/h$ is called the threshold frequency. The term V_0e represents the work spent in getting the electron out of the substance illuminated by the light; in the case of metals probably the bulk of this is accounted for by the attraction between the electron when just outside the surface and its image in the conducting surface; this requires an amount of work $e^2/4r$, when r is the distance of the electron from the surface, to be spent by the electron in getting away from the surface. If r equals 10^{-8} the radius of an atom, this effect would add $3{\cdot}6$ volts to V_0.

The value of the threshold wave lengths for metals in normal conditions (surfaces sand-papered but not otherwise treated) as given by Hamer (*Optical Soc. of Amer. Journal* ix. p. 251, 1924) are:

Ag.	Al.	Bi.	Graphite	Ca.	Cd.	Cu.	Fe.
3,390	3,590	2,980	2,615	4,000	3,130	2,665	2,870
Ni.	**Pb.**	**Pt.**	**Se.**	**Sn.**	**Th.**	**W.**	**Zn.**
3,050	2,980	2,780	2,670	3,180	3,460	2,615	3,420

The metals were *in valuo.*

Measurements such as those made by Pohl and Pringsheim (*Verh. d. Deutsch. Phys. Gesell.* xv. p. 173, 1913), show that the sum of the energies of the ejected electrons is but a small percentage of the energy of the light which ejects them.

The photo-electric effect is applied in the photo-electric cell to the measurement of very small intensities of light. The alkali metals have chiefly been used for this purpose and have proved very successful. The sensitiveness of these cells can be much increased by passing a slow discharge through them when a little hydrogen has been admitted into the cell. This causes the formation of a hydride, and probably turns the rest of the metal into a very sensitive colloidal form. The cell is then filled with an inert gas, such as argon, at a pressure of about 1 mm. This does not affect the surface of the metal and allows the current due to the photo-electric effect to be increased by ionization by collision.

Photo-electric Properties of Gases.—If light is able to eject electrons from the molecules of a gas it must clearly increase its conductivity, the residues of the molecules forming positive ions and the electrons being either free or attached to neutral molecules forming the negative ions. Early experiments on conductivity in this point gave rather contradictory results. It is now known that in most cases it requires light of shorter wave length to give a photo-electric effect than the majority of solids, and in consequence there is great danger of spurious effects due to electrons emitted by dust particles or by the walls of the vessel. Hughes (*Proc. Camb. Phil. Soc.* 15, 483, 1910) detected the presence of positive ions in air when it was exposed to the light emitted by an electric discharge through hydrogen if the light went through a fluorite window, though no such effect was produced if the light passed through quartz, which is not transparent for light of shorter wave length than 1,450. Palmer (*Phys. Rev.* 32, p. 1, 1911) also found ionization in air, oxygen and nitrogen from light which had passed through fluorite. Lenard and Ramsauer found that minute traces of impurities both gaseous and solid had an enormous effect on the ionization. Traces of ammonia and carbon dioxide increased the ionization for light through fluorite by 44 and 16 times respectively.

Stark (*Phys. Zeit.* x. p. 787, 1909) found marked ionization in various fluorescent vapours, such as those of anthracene, diphenylmethane, α naphthylamine and diphenylamine, by the light from a mercury lamp transmitted through quartz. This light can also ionize the vapours of the alkali metals.

Ionization by Collision.—When the ionization of the gas is produced by external agents such as Röntgen rays or ultra-violet light, the electric field produces a current by setting the positive

ions moving in one direction, and the negative ones in the opposite; it makes use of ions already made and does not itself give rise to ionization. In many cases, however, such as in electric sparks, there are no external agents to produce ionization and the electric field has to produce the ions as well as set them in motion. When the ionization is produced by external means the smallest electric field is able to produce a current through the gas; when, however, these external means are absent no current is produced unless the strength of the electric field exceeds a certain critical value, which depends not merely upon the nature of the gas, but also upon the pressure and the dimensions of the vessel in which it is contained. These variations in the electric field required to produce discharge can be completely explained if we suppose that the ionization of the gas is produced by the impact with its molecules of electrons, and in certain cases of positive ions, which under the influence of the electric field have acquired considerable kinetic energy. We have direct evidence that rapidly moving electrons are able to ionize molecules against which they strike, for the cathode rays consist of such electrons, and these when they pass through a gas produce large amounts of ionization.

Suppose, then, that we have in a gas exposed to an electric field a few electrons. These will be set in motion by the field and will acquire an amount of energy in proportion to the product of the electric force, their charge, and the distance travelled in the direction of the electric field between two collisions with the molecules of the gas. If this energy is sufficient to give them the ionizing property possessed by cathode rays, then when an electron strikes against a molecule it will detach another electron; this under the action of the electric field will acquire enough energy to produce electrons on its own account, and so as the electrons move through the gas their number will increase in geometrical progression. Thus, though there were but few electrons to begin with, there may be great ionization after these have been driven some distance through the gas by the electric field.

The number of ions produced by collisions can be calculated by the following method. Let the electric force be parallel to the axis of x, and let n be the number of electrons per unit volume at a place fixed by the co-ordinate x; then in unit time these electrons will make n/λ collisions with the molecules, if u is the velocity of an electron and λ its mean free path. When the electrons are moving fast enough to produce ions by collision their velocities are very much greater than those they would possess at the same temperature if they were not acted on by electrical force, and so we may regard the velocities as being parallel to the axis of x and determined by the electric force and the mean free path of the electrons. We have to consider how many of the nu/λ collisions which take place per second will produce ions. The ionization of a molecule will require a certain amount of energy, so that if the energy of the electron falls below this amount no ionization will take place, while if the energy of the electron exceeds this limit a collision might result in ionization. We shall suppose that a certain fraction of the number of collisions result in ionization and that this fraction is a function of the energy possessed by the electron when it collides against the molecules. This energy is proportional to $Xe\lambda$ when X is the electric force, e the charge on the electron, and λ the mean free path. If the fraction of collisions which produce ionization is $f(Xe\lambda)$ then the number of ions produced per cubic centimetre per second is $f(Xe\lambda)nu/\lambda$.

If the collisions follow each other with great rapidity so that a molecule has not had time to recover from one collision before it is struck again, the effect of collisions might be cumulative, so that a succession of collisions might give rise to ionization, though none of the collisions would produce an ion by itself. In this case f would involve the frequency of the collisions as well as the energy of the electron; in other words, it might depend on the current through the gas as well as upon the intensity of the electric field. We shall, however, to begin with, assume that the current is so small that this cumulative effect may be neglected.

Let us now consider the rate of increase, dn/dt, in the number of electrons per unit volume. In consequence of the collisions, $f(Xe\lambda)nu/\lambda$ electrons are produced per second; in consequence of the motion of the electrons, the number which leave unit volume per second is greater than those which enter it by $\frac{d}{dx}(nu)$; while in a certain number of collisions an electron will stick to the molecule and will thus cease to be a free electron. Let the fraction of the number of collisions in which this occurs be β. Thus the gain in the number of electrons is $f(Xe\lambda)nu/\lambda$, while the loss is $\frac{d}{dx}(nu)+\beta\frac{nu}{\lambda}$; hence

$$\frac{dn}{dt}=f(Xe\lambda)\frac{nu}{\lambda}-\frac{d}{dx}(nu)-\frac{\beta nu}{\lambda}.$$

When things are in a steady state $dn/dt=0$, and we have

$$\frac{d}{dx}(nu)=\frac{1}{\lambda}\{f(Xe\lambda)-\beta\}nu.$$

If the current is so small that the electrical charges in the gas are not able to produce any appreciable variations in the field, X will be constant and we get $nu=C\epsilon^{\alpha x}$, where $\alpha=\{f(Xe\lambda)-\beta\}/\lambda$. If we take the origin from which we measure x at the cathode, C is the value of nu at the cathode, *i.e.*, it is the number of electrons emitted per unit area of the cathode per unit time; this is equal to i_0/e if i_0 is the quantity of negative electricity coming from unit area of the cathode per second, and e the electric charge carried by an electron. Hence we have $nue=i_0\epsilon^{\alpha x}$. If l is the distance between the anode and the cathode, the value of nue, when $x=l$, is the current passing through unit area of the gas, if we neglect the electricity carried by negatively electrified carriers other than electrons. Hence $i=i_0\epsilon^{\alpha l}$. Thus the current between the plates increases in geometrical progression with the distance between the plates.

By measuring the variation of the current as the distance between the plates is increased, Townsend, to whom we owe much of our knowledge on this subject, determined the values of α for different values of X and for different pressures for air, hydrogen and carbonic acid gas (*Phil. Mag.* [6], 1, p. 198). Since λ varies inversely as the pressure, we see that α may be written in the form $p\phi(X/p)$ or $\alpha/X=F(X/p)$. The following are some of the values of α found by Townsend for air.

X Volts per cm.	Pressure ·17 mm.	Pressure ·38 mm.	Pressure 1·10 mm.	Pressure 2·1 mm.	Pressure 4·1 mm.
20	·24	..	..	..	..
40	·65	·34	..	..	..
80	1·35	1·3	·45	·13	..
120	1·8	2·0	1·1	·42	·13
160	2·1	2·8	2·0	·9	·28
200	..	3·4	2·8	1·6	·5
240	2·45	3·8	4·0	2·35	·99
320	2·7	4·5	5·5	4·0	2·1
400	..	5·0	6·8	6·0	3·6
480	3·15	5·4	8·0	7·8	5·3
560	..	5·8	9·3	9·4	7·1
640	3·25	6·2	10·6	10·8	8·9

We see from this table that for a given value of X, α for small pressures increases as the pressure increases; it attains a maximum at a particular pressure, and then diminishes as the pressure increases. The increase in the pressure increases the number of collisions, but diminishes the energy acquired by the electron in the electric field, and thus diminishes the chance of any one collision resulting in ionization. If we suppose the field is so strong that at some particular pressure the energy acquired by the electron is well above the value required to ionize at each collision, then it is evident that increasing the number of collisions will increase the amount of ionization, and therefore α and α cannot begin to diminish until the pressure has increased to such an extent that the mean free path of an electron is so small that the energy acquired by the electron from the electric field falls below the value when each collision results in ionization.

The value of p, when X is given, for which α is a maximum, is

proportional to X; this follows at once from the fact that α is of the form $X \cdot F(X/p)$. The value of X/p for which $F(X/p)$ is a maximum is seen from the preceding table to be about 420, when X is expressed in volts per centimetre and p in millimetres of mercury. The maximum value of $F(X/p)$ is about 1/60. Since the current passing between two planes at a distance l apart is $i_0\epsilon^{\alpha l}$ or $i_0\epsilon^{XlF(X/p)}$, and since the force between the plates is supposed to be uniform, Xl is equal to V, the potential between the plates; hence the current between the plates is $i_0\epsilon^{V \cdot F(X/p)}$, and the greatest value it can have is $i_0\epsilon^{V/60}$. Thus the ratio between the current between the plates when there is ionization and when there is none cannot be greater than $\epsilon^{V/60}$, when V is measured in volts. This result is based on Townsend's experiments with very weak currents; we must remember, however, that when the collisions are so frequent that the effects of collisions can accumulate, α may have much larger values than when the current is small. In some experiments made by J. J. Thomson with intense currents from cathodes covered with hot lime, the increase in the current when the potential difference was 60 volts, instead of being e times the current when there was no ionization, as the preceding theory indicates, was several hundred times that value, thus indicating a great increase in α with the strength of the current.

Townsend has shown that we can deduce from the values of α the mean free path of an electron. For if the ionization is due to the collisions with the electrons, then unless one collision detaches more than one electron the maximum number of electrons produced will be equal to the number of collisions. When each collision results in the production of an electron, $\alpha = 1\lambda$ and is independent of the strength of the electric field. Hence we see that the value of α when it is independent of the electric field, is equal to the reciprocal of the free path. Thus from the table we infer that at a pressure of 17 mm. the mean free path is $\frac{1}{325}$ cm.; hence at 1 mm. the mean free path of an electron is $\frac{1}{19}$ cm. Townsend has shown that this value of the mean free path agrees well with the value $\frac{1}{21}$ cm. deduced from the kinetic theory of gases for an electron moving through air. By measuring the values of α for hydrogen and carbonic acid gas Townsend and Kirby (*Phil. Mag.* [6], 1, p. 630) showed that the mean free paths for electrons in these gases are respectively $\frac{1}{11.8}$ and $\frac{1}{29}$ m. at a pressure of 1 mm. These results again agree well with the values given by the kinetic theory of gases.

If the number of positive ions per unit volume is m and v is the velocity, we have $nue + mve = i$, where i is the current through unit area of the gas. Since $nue = i_0\epsilon^{\alpha x}$ and $i = i_0\epsilon^{\alpha l}$ when l is the distance between the plates, we see that

$$nu/mv = \epsilon^{\alpha x}/(\epsilon^{\alpha l} - \epsilon^{\alpha x}),$$

$$\frac{n}{m} = \frac{v}{u} \cdot \frac{\epsilon^{\alpha x}}{\epsilon^{\alpha l} - \epsilon^{\alpha x}}.$$

Since v/u is a very small quantity we see that n will be less than m except when $\epsilon^{\alpha l} - \epsilon^{\alpha x}$ is small; *i.e.*, except close to the anode. Thus there will be an excess of positive electricity from the cathode almost up to the anode, while close to the anode there will be an excess of negative. This distribution of electricity will make the electric force diminish from the cathode to the place where there is as much positive as negative electricity, where it will have its minimum value, and then increase up to the anode.

The expression $i = i_0\epsilon^{\alpha l}$ applies to the case when there is no source of ionization in the gas other than the collisions; if in addition to this there is a source of uniform ionization producing q ions per cubic centimetre we can easily show that

$$i = i_0\epsilon^{\alpha l} + \frac{q\epsilon}{\alpha}(\epsilon^{\alpha l} - 1).$$

With regard to the minimum energy which must be possessed by an electron to enable it to produce ions by collision, Townsend (*loc. cit.*) came to the conclusion that to ionize air the electron must possess an amount of energy equal to that acquired by the fall of its charge through a potential difference of about 2 volts. This potential difference is called the ionizing potential; it has been determined by other methods for many gases. The values so obtained are very much greater than those deduced by Townsend from ionization by collision. Partysch (*Verh. deutsche. Phys. Gesell,* 14, 60, 192) has suggested that since there can be no ionization until the electron has acquired energy equal to that required to ionize the gas and that it cannot have acquired this until it has moved through a distance P/X where P is ionizing potential l in these formulae should be replaced by $l - \frac{P}{X}$.

If there is no external source of ionization and no emission of electrons from the cathode, then it is evident that even if some electrons happened to be present in the gas when the electric field were applied, we could not get a permanent current by the aid of collisions made by these electrons. For under the electric field, the electrons would be driven from the cathode to the anode, and in a short time all the electrons originally present in the gas and those produced by them would be driven from the gas against the anode, and if there was no source from which fresh electrons could be introduced into the gas the current would cease. The current, however, could be maintained indefinitely if the positive ions in their journey back to the cathode also produced ions by collisions, for then we should have a kind of regenerative process by which the supply of electrons could be continually renewed. To maintain the current it is not necessary that the ionization resulting from the positive ions should be anything like as great as that from the electrons. The mass of the positive ion is so much greater than that of an electron that in a collision between them only a very small fraction of the energy of the ion is transferred to the electron. To enable the positive ion to ionize, the electric field must be very intense, much more intense than that which experience shows is sufficient to maintain the discharge. Another method by which the current could be and is maintained is by the cathode emitting electrons under the impact of the positive ions driven against it by the electric field. J. J. Thomson has shown by direct experiment that positively electrified particles when they strike against a metal plate cause the metal to emit electrons (J. J. Thomson, *Proc. Camb. Phil. Soc.* 13, p. 212; Austin, *Phys. Rev.* 22, p. 312). If we assume that the number of electrons emitted by the plate in one second is proportional to the energy in the positive ions which strike the plate in that second, we can readily find an expression for the difference of potential which will maintain without any external ionization a current of electricity through the gas.

Two methods suggest themselves by which the electrons might be emitted from the cathode under the influence of the positive ions; the first of these is that at the cathode the positive ions are neutralized by the return of an electron; this gives rise to radiation and this radiation falling on the cathode will, by the photo-electric effect, produce an emission of electrons from the cathode. The second method is that since the positive ions possess a large amount of energy, their impact against the cathode will raise its temperature at the places where they strike and thus produce a thermionic emission. In the first method the emission of the electrons would depend primarily on the number of positive ions striking against the cathode, while in the second method it would depend upon the energy these ions possess as well as upon their number.

In addition to the effects taking place at the cathode there are other agencies which could produce the regenerative effect. The discharge through the gas produces soft X-ray radiation of much shorter wave length than any which can pass through glass or quartz, and which, in fact, is absorbed by a few millimetres of gas even at a comparatively low pressure. This radiation has the power of ionizing the gas and as it travels backwards from the electrons as well as forwards it supplies ions in the rear of the electrons and thus maintains the discharge.

We may thus divide the ionization in the self-sustained discharge into three categories:

(1) A volume ionization due to the collision of electrons.
(2) Processes taking place at the cathode.
(3) A volume ionization.

We shall consider more closely the ionization due to the collisions of electrons. If the electron is to ionize the gas it must

possess energy greater than that required to eject an electron from a molecule, let this energy be represented by Pe, where e is the charge on an electron, P is called the ionizing potential of the molecule. To be able to ionize the gas, the electron must possess energy due to a fall through a potential difference greater than P. As the energy of the electron increases, the chance of its ejecting an electron by collision does not increase indefinitely with the energy, it attains a maximum for a particular value of the energy after which it diminishes rapidly. From the theory of the transference of energy by collision it follows that the chance that an electron whose energy is measured by V should ionize on collision is proportional to

$$\frac{V-P}{1+\left(\frac{V-P}{Q}\right)^2}$$

where Q is the value of $V-P$ when the chance is a maximum, hence if ω represents the maximum chance, the chance when the energy is V is

$$\frac{2\omega\cdot\frac{V-P}{Q}}{1+\left(\frac{V-P}{Q}\right)^2} \tag{1}$$

This quantity is the one denoted by $f(Xe\lambda)$, hence by an equation previously given

$$\frac{d}{dx}nu=\frac{nu}{\lambda}\left\{\frac{2\omega\,\frac{V-P}{Q}}{1+\left(\frac{V-P}{Q}\right)^2}-\beta\right\} \tag{2}$$

$$=\theta\cdot\frac{nu}{\lambda} \tag{3}$$

where θ is written for the expression inside the bracket on the right-hand side of equation (2). The solution of equation (3) is

$$\log nu=\frac{\theta}{\lambda}x+c. \tag{4}$$

Let d be the distance between the electrodes, then when $x=d$ $nu=i/e$ where i is the current through unit area of the gas, and when $x=0$ $nu=i_0/_e$ where i_0 is the number of electrons emitted by unit area of the cathode in unit time. From these conditions we find from equation (4)

$$\log\frac{i}{i_0}=\frac{\theta d}{\lambda}. \tag{5}$$

The current carried by the positive ions at the cathode is equal to $i-i_0$, denoting this current by i, equation (5) may be written

$$\log\frac{(i_p+i_0)}{i_0}=\theta\cdot\frac{d}{\lambda} \tag{6}$$

The current i_0 is due to the impact of the positive charges, if it arises from a photo-electric effect due to the neutralization of the charges, i_0 will be a constant multiple of i_p. If each positive ion on neutralization emits radiation which ejects γ electrons from the cathode $i_0=i_p$ and (6) becomes

$$\log\frac{1+\gamma}{\gamma}=\frac{\theta d}{\lambda}. \tag{7}$$

When $V-P$ is small compared with Q, as it will be when the current through the gas is small, we see from (2) that

$$\theta=\frac{2\omega(V-P)}{Q}-\beta$$

and since $V=X\lambda$ we get from (7)

$$\log\frac{1+\gamma}{\gamma}=2\left(Xd-\frac{Pd}{\lambda}\right)\frac{\omega}{Q}-\beta\cdot$$

If E is the potential difference between the electrodes when the spark is passing $E=Xd$; hence

$$E=\frac{Q}{2\omega}\left(\log\frac{(1+\gamma)}{\gamma}+\beta\right)+\frac{Pd}{\lambda}. \tag{8}$$

Thus the potential difference required to spark across a distance d is a linear function of d/λ and cannot fall below a certain value. This is in agreement with the experimental results. It is to be noticed that d only occurs in the combination d/λ, since for the same gas λ is inversely proportional to p we see that E will be a function of dp, the quantity of gas between the electrodes is proportional to dp, hence we see that as long as this remains the same the sparking potential will be unaltered, whether we have a thin layer of gas at a high pressure or the same quantity in a thicker layer at a low pressure. This result, which holds with great accuracy, was discovered by Paschen and is known as Paschen's Law.

Let us now turn to the case of very short sparks: since the maximum value of θ is $\omega-\beta$ it follows from (7) that d/λ cannot be less than $\frac{1}{\omega-\beta}\log\frac{1+\gamma}{\gamma}$ hence if the photo-electric effect were the only agency at work it would be impossible to produce sparks shorter than a certain critical length. This would not necessarily be true if the emission of electrons from the cathode were partly thermionic for then γ would not be constant but would depend on the energy of the positive ion when it struck the cathode; this would increase with E. Let us suppose for example that γ is proportional to E, then since when γ is large

$$\log\left(\frac{1+\gamma}{\gamma}\right)=\frac{1}{\gamma}$$

the equation (7) would take the form

$$\frac{1}{\gamma}=\frac{d}{\lambda}\theta$$

or since γ is proportional to E

$$Ed\theta/\lambda=\text{a constant.}$$

Thus, though E would increase rapidly when d/λ is small there would be no critical value of d/λ below which no discharge would take place. The experiments made on short sparks seem in accordance with this view. Let us now consider the effect that would be produced by radiation excited by the discharge; if the ionization due to this per unit volume is equal to Qp when p is the density of the gas, in this case instead of equation (3) we have

$$\frac{d}{dx}(nu)=\theta\frac{nu}{\lambda}+Qp.$$

The solution when Q is constant is

$$nu=\frac{-Qp\lambda}{\theta}+C_{i_0\epsilon}\frac{\theta x}{\lambda}\cdot$$

If i is the current through the gas the electron current at the cathode, $nu=i/e$ when $x=d$ and $i_{0/e}$ when $x=0$, hence

$$\frac{i}{e}=\frac{Qp\lambda}{\theta}\left(\epsilon\frac{\theta d}{\lambda_{-1}}\right)+\frac{\omega}{\epsilon}e\frac{\theta d}{\lambda}\cdot \tag{1}$$

When there are neither photo-electric nor thermionic effects at the cathode, $i_0=0$ and

$$\frac{i}{e}=\frac{Qp\lambda}{\theta}\left(\epsilon\frac{\theta d}{\lambda_{-1}}\right) \tag{2}$$

Now $Q'p/(i\theta/e\lambda)$ is the ratio of the ionization due to radiation to that due to collisions made by the electrons and this is usually a very small quantity; let us denote it by $1/\gamma$. Then from (2)

$$\frac{\theta d}{\lambda}=\log(1+\gamma)$$

a relation of exactly the same form as that we obtained when we supposed that the only volume ionization was that due to collision, but that this was supplemented by emission of electrons from the cathode. Hence for long sparks the relation between spark potential and spark length will be the same on either theory. For very short spark lengths, we see from (2) that

$$\frac{i}{e} = Qpd \tag{3}$$

If the energy in the radiation is proportional to the work put into the discharge Q is proportional to Vi let Q$=p$Vi, then from (3)

$$V = \frac{1}{pepd}$$

Thus the potential difference required to produce a very short spark varies inversely as the spark length; we see that in this case also Paschen's law holds since V is a function of pd. Since the spark potential is infinite when the spark length is infinite and also when it is zero, there must be some length, which by Paschen's law will be inversely proportional to the pressure when the spark potential is a minimum; this potential is called the critical spark potential and the corresponding spark length the critical spark length. Since all the theories give practically the same results for long sparks it would seem that the decision between them must be made on short sparks, *i.e.*, on sparks shorter than the critical spark length.

Hitherto we have supposed that the electric force is constant between the electrodes, but it is easy to see that when the spark length is greater than the critical value the discharge in a non-uniform field might be produced by a smaller potential difference than in a uniform one.

For suppose that C represents the cathode, A the anode, B a plane whose distance from C is equal to l, the critical spark length. If a potential difference equal to the critical potential exists between C and B, then this region can furnish a continuous supply of electrons and all that is necessary to maintain the discharge is that the electric force from B to A should be great enough to remove the electrons as fast as they are produced and prevent a continuous increase in the number of electrons between B and A, which would tend to stop the discharge. The force required to do this need not be large enough to make the electrons produce other electrons by collisions, thus in consequence of the smallness of the force between B and A the potential difference may be much smaller than if the field were uniform. The potential difference between B and A may be calculated from the expression given for the space charge effect; it will be seen that the potential difference is proportional to $i^{\frac{1}{2}}$ and l where i is the current and l=AB; thus it increases more quickly with the distance than if the field were uniform. After a certain value of l the electric force will be great enough to cause ionization by collision and the field may again become uniform. The want of uniformity in the field requires in conformity with the equation $dX/dn = 4\pi\rho$ an accumulation of ions. Until these are available the field must be uniform and therefore the potential difference required to spark greater than that necessary after the ions have accumulated.

We have evidence of this in what is called the "lag" in the discharge; in many cases there is a considerable interval between the application of the electric field and the passage of the spark. This may be regarded as the time necessary for the ions to accumulate in sufficient numbers to produce the want of uniformity in the field necessary to produce the diminution in the spark potential. Warburg has shown that the lag is diminished when the cathode is illuminated by ultra-violet light, while with Röntgen rays which ionize the gas the illumination of the gas without that of the cathode has been found by Elster to diminish the lag. Warburg showed that when the ions were removed by a magnet as fast as they were produced the lag was increased very greatly. Even when the sparks are short we should expect that non-uniform field would produce the discharge with a smaller potential difference than a uniform one. For the sooner the electrons coming out of the cathode acquire enough energy to ionize by collision the more electrons will they produce before they reach the anode. From this point of view it is thus more advantageous to have the electric force larger at the cathode and smaller at the anode than to have it uniform even though the average value remains the same. This non-uniform electric force will involve a finite density of ions in the path of the discharge and therefore a finite current density, so that we should expect that when the discharge has got into a steady state and is passing with the minimum potential difference the current density must have a definite value which will increase with the pressures.

This is in accordance with the behaviour of the discharge, for if we apply to the electrodes a considerable potential difference but one not sufficient to produce a discharge at atmospheric pressure and then gradually reduce the pressure until the discharge begins to pass, as first it only comes from a very small area of the cathode as the pressure is reduced this area increases until it covers the whole of the cathode, this increase in the area decreases the current density for the total current does not increase in anything like the same proportion.

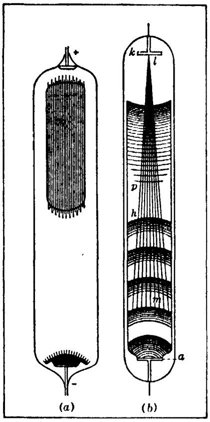

FIG. 11

Conduction Through Gases at Low Pressures.—The inequality of the electric field in the gas when a continuous discharge is passing through it is very obvious when the pressure of the gas is low. In this case the discharge presents a highly differentiated appearance of which a type is represented in fig. 11. Starting from the cathode we have a thin velvety luminous glow in contact with the surface of the metal. This glow is often called the *first cathode layer*. Next this we have a comparatively dark space whose thickness increases as the pressure diminishes; this is called the *Crookes' dark space*, or the *second cathode layer*. Next this we have a luminous position called the *negative glow* or the *third cathode layer*. The boundary between the second and third layers is often very sharply defined. Next to the third layer we have another dark space called the *Faraday dark space*. Next to this and reaching up to the anode is another region of luminosity, called the *positive column*, sometimes (as in fig. 11, *a*) continuous, sometimes (as in fig. 11, *b*) broken up into light or dark patches called *striations*. The dimensions of the Faraday dark space and the positive column vary greatly with the current passing through the gas and with its pressure; sometimes one or other of them is absent. These differences in appearances are accompanied by great differences in the strength of the electric field. The magnitude of the electric force at different parts of the discharge is represented in fig. 12, where the ordinates represent the electric force at different parts of the tube, the cathode being on the right. We see that the electric force is very large indeed between the negative glow and the cathode, much larger than in any other part of the tube. It is not constant in this region, but increases as we approach the cathode. The force reaches a minimum either in the negative glow itself or in the part of the Faraday dark space just outside, after which it increases towards the positive column. In the case of a uniform positive column the electric force along it is constant until we get quite close to the anode, when a sudden change, called the *anode fall*, takes place in the potential.

The difference of potential between the cathode and the negative glow is called the *cathode potential fall* and is found to be constant for wide variations in the pressure of the gas and the current passing through, provided the whole of the cathode is not covered with the glow. It increases, however, considerably when the current through the gas exceeds a certain critical value, just sufficient to cover the whole of the cathode with the glow, this value depends among other things on the size of the cathode. The cathode fall of potential is shown by experiment to be very approximately equal to the minimum potential difference required to produce a spark. The following table contains a comparison of the measurements of the cathode fall of potentials in various

gases made by Warburg (*Wied. Ann.*, 1887, 31, p. 545, and 1890, 40, p. 1), Capstick (*Proc. Roy. Society*, 1898, 63, p. 356); and Strutt (*Phil. Trans.*, 1900, 193, p. 377); and the measurements by Strutt of the smallest difference of potential which will maintain a spark through these gases.

Gas	Cathode fall in volts				Least potential difference required to maintain a spark
	Platinum electrodes			Aluminium electrodes	
	Warburg	Capstick	Strutt	Warburg	Strutt
Air	340–350	..	..	..	341
H_2	About 300	298	..	168	302–308
O_2	..	369	..	..	..
N_2	230 if free from oxygen	232	..	207	251
Hg vapour	340	..	..	..	..
Helium	..	..	226	..	261 326
H_2O	..	469	..	..	..
NH_3	..	582	..	..	..

Thus in the cases in which the measurements could be made with the greatest accuracy the agreement between the cathode fall and the minimum potential difference is very close. The cathode fall depends on the material of which the terminals are made, as is shown by the following table due to Mey (*Verh. deutsch. physik. Gesell.*, 1903, 5, p. 72).

Gas	Electrode										
	Pt	Hg	Ag	Cu	Fe	Zn	Al	Mg	Na	Na-K	K
O_2	369	..	..	..	..	..	..	..	..	..	..
H_2	300	..	295	280	230	213	190	168	185	169	172
N_2	232	226	..	..	..	..	..	207	178	125	170
He	226	..	..	..	..	..	..	..	80	78·5	69
Argon	167	..	..	..	..	..	100	..	..	..	..

The dependence of the minimum potential required to produce a spark upon the metal of which the cathode is made has not been clearly established, some observers being unable to detect any difference between the potential required to spark between electrodes of aluminium and those of brass, while others thought they had detected such a difference. It is only with sparks not much longer than the critical spark length that we could hope to detect this difference. When the current through the gas exceeds a certain critical value depending among other things on the size of the cathode, the cathode fall of potential increases rapidly and at the same time the thickness of the dark spaces diminishes. We may regard the part of the discharge between the cathode and the negative glow as a discharge taking place under minimum potential difference through a distance equal to the critical spark length. An inspection of fig. 12 will show that we cannot regard the electric field as constant even for this small distance.

Electric Force in Cathode Dark Space.—The cathode dark space, which is very conspicuous when the pressure of the gas is low, gives us a picture of a discharge passing with the minimum potential difference, the study of which throws a great deal of light on the mechanism of the spark discharge.

In the first place the electric force in the dark space is not constant but as we might expect is greatest close to the cathode. Aston (*Proc. Roy. Soc.*, 84A, p. 526), who has made many experiments on this point, finds that for the normal discharge the electric force at any point in the dark space is directly proportional to the distance of the point from the end of the dark space. Thus if the thickness of the dark space is d the force at a distance x from the cathode is equal to $C(d-x)$, if this is the value of force the difference of potential between the cathode and the end of the dark space is $\frac{1}{2}Cd^2$, this difference is called the cathode fall of potential, we shall denote it by K, the force at the point x is thus $2K(d-x)/d^2$. From the equation $dX/dx=4\pi\rho$ it follows that the density of the electrification in the dark space is positive and constant and equal to $K2\pi d^2$. Now d varies inversely as the pressure of the gas so that the density of the electrification varies directly as the square of the pressure.

The cathode fall of potential depends upon the material of the electrode and the nature of the gas. It is in many cases very sensitive to impurities either in the metal of the cathode or in the gas; traces of alkali metals on the cathode or of water vapour

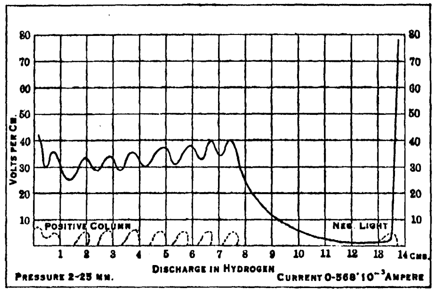

FIG. 12

in the gas produce especially large effects, and it is important in making measurements on this quantity to heat the cathode so as to free it from the layers of gas with which it may happen to be coated. The current density i_n in the normal discharge is also a quantity of fundamental importance depending on the gas and on the electrode. With plane electrodes i_n varies as the square of the pressure, with cylindrical electrodes it is proportional to the pressure.

Günter-Schultze who has made most important investigations on the dark space gives the following values for K_n in volts and for i_n in amperes per square centimetre at 1 mm. pressure (*Zeit. f. Physik.* 20, 1, 1923).

	Aluminium electrode		Iron electrode	
Gas	K_n	$i_n \times 10^6$	K	$i_n \times 10^6$
He	153	1·072	161	1·187
Ne	145	1·81	153	2·00
Ar	150	14·07	166	15·5
N	215	38·4	256	42·3
H	192	9·00	250	9·96
O	250	54·7	326	60·6

The normal current densities in the different gases vary much more than the critical potentials.

The thickness of the dark space, as long as the gas and electrode are the same, varies as long as the discharge is normal inversely as the pressure; the product pd depends however upon the gas and upon the electrode, as the following table due to Günter-Schultze shows, p being measured in millimetres of mercury and d in centimetres.

Gas	Cathode	pd.
He	Al	1·32
He	Fe	1·66
Ne	Al	·637
Ne	Fe	·722
Argon	Al	·285
Argon	Fe	·356
N	Al	·305
N	Fe	·419
H	Al	·724
H	Fe	·900

Günter-Schultze (*l.c.*) finds that the current density i, the potential fall K and the thickness of the dark space d are connected by a relation similar to that which holds for the space charge, viz.:

$$i=\frac{\sqrt{2}}{9\pi}\int\frac{e}{n}\cdot\frac{K^{\frac{3}{2}}}{d^2}$$

when M is the mass of the positive ion and e its charge. It may be pointed out that both a relation of this kind and Aston's law of force in the dark space would follow from the supposition that the ionization is constant throughout the dark space and that the current is carried by the positive ions. Günter-Schultze has shown that the values of K for different metals in the same gas are closely related to their photoelectric "threshold" potentials.

The preceding remarks apply only when the discharge is normal *i.e.*, when the cathode is large enough to permit the current to go through the tube without exceeding the normal current density and also when the space surrounding the cathode is large enough to allow the dark space to be fully developed and not interrupted by the walls of the tube. If the cathode is constricted the cathode potential fall increases rapidly just for the same reason that the spark potential increases rapidly when the spark length is reduced below the critical value. When the current is increased until the glow covers the whole of the cathode and the current density is necessarily greater than the normal, the cathode fall increases as the current increases while the thickness of the dark space diminishes. Aston (*Proc. Roy. Soc.*, 86, p. 178) gives the following empirical relations between d, the thickness of the dark space, K, the potential fall, i, the current and p, the pressure, when the discharge is not normal.

$$d=\frac{A}{P}+\frac{B}{\sqrt{i}}$$

$$K=E+\frac{F\sqrt{i}}{p}$$

where A, B, E, F are constants depending on the electrode and on the gas. Günter-Schultze gives as an empirical relation holding at constant pressure

$$K=(\text{Constant})\ i^{\frac{1}{2}}.$$

The Negative Glow.—Let us now consider the region just beyond the dark space. At the end of the dark space there will be a current of electrons some of which have started from the cathode and have acquired the energy due to the cathode fall of potential, others which have originated in the dark space itself will not have so much energy. There will thus be a stream of energy passing out into the adjacent region. This energy will be sufficient to ionize a large number of molecules without any help from outside. The local field has not to supply energy to ionize the gas but merely to give a drift to ions made without its assistance. For this a very small field will suffice and in the negative glow the field is so small that there is often not a difference of potential of a volt from one end to the other. Thus to produce a spark whose length is equal to the dark space plus the length of the negative glow requires hardly any greater potential difference than to produce one whose length is equal to the dark space.

The stream of electrons as it passes through the negative glow is continually losing energy and after going a certain distance has lost so much that it is no longer able to ionize the gas. When this occurs the electrons which come out of the glow will be moving in a region where there is no ionization and no positive ions to balance the charge on the electron. There will thus be a space charge effect and the potential will rise according to the law

$$V\alpha(ix^2)^{\frac{2}{3}}$$

where i is the current and x the distance from the negative glow. Until x is large enough to make V equal to the resonance potential (*q.v.*) of the gas there will be no luminosity. This region is the Faraday dark space; when V equals one of the resonance potentials luminosity will begin but there will be no ionization until V reaches the ionization potential of the gas. Then ionization will begin and the potential will not increase so rapidly as it did in the Faraday dark space. It may, however, still continue to increase and under certain conditions may rise considerably above the ionization potential.

In this case the electrons may have acquired so much energy that like those in the negative glow they are able to ionize with little or no further assistance from the local field and we shall have a region analogous to the negative glow where the electric force is very small. The energy of the electrons will be exhausted after passing through a certain thickness and then we shall have a region corresponding to the Faraday dark space in which the electric field increases until another negative glow is produced, and the cycle begins again. Thus in this case the discharge would consist of a regular alternation of bright and dark regions such as we have in the striated positive column.

There is, however, another way in which the charge may be maintained. The electric field instead of being variable producing a large supply of ions in some places and none in others, might be constant throughout producing just enough new electrons to supply the loss of the old ones due to combination with positive ions, attachment to molecules, diffusion to the sides of the discharge tube, and other causes.

From a previous equation we see that the chance of an electron detaching another electron by a collision is

$$\frac{2w}{Q}(X\lambda-P)$$

If the chance that the electron should from one or the other of the causes just mentioned be lost at the collision be β then if

$$\frac{2w}{Q}(X\lambda-P)=\beta$$

the losses will be balanced by the gains and a shady state maintained. Thus if

$$X=\frac{P}{\lambda}+\frac{\beta}{\lambda}\frac{Q}{2w}$$

a steady discharge is possible, the conditions now do not vary along this part of the discharge, and it would show all the characteristics of the uniform positive column.

Whether the discharge is striated or continuous will be determined by the condition that the discharge will tend to pass with the minimum potential difference; the positive column will be continuous if the potential difference is less for this type of discharge than for the striated one while if it is greater the discharge will be striated. So many factors have to be taken into account that the problem of determining which of these forms of discharge might be expected to give the smaller potential difference is an exceedingly complicated one. We shall only give some quite general considerations to show that we might expect the advantage to change from one form to the other under certain changes in the conditions. The criterion which determines whether the discharge is striated or continuous is whether the change from the striated to the continuous form would increase or decrease the potential difference on a given length of the column, or what amounts to the same thing whether the force in the continuous column is less or greater than the average force in the striated one. The conditions which might be expected to increase the force in the continuous column relatively to that in the striated may be deduced by the consideration of equation (7).

We shall confine ourselves to the effect of the term represented by β for changes in λ would affect the striated column in the same direction though not necessarily to the same extent. The term in β is proportional to the loss of electrons in various ways; some of these ways, such as the loss by the diffusion of electrons which, as it is larger in small tubes than in large, makes the electric force necessary to sustain the discharge greater in small tubes than in large, will affect the striated discharge in the same way. It will make the potential due to the space charge effect increase more rapidly with the distance when electrons diffuse to the sides as those which remain will have to be speeded up to carry the same current. There is, however, another source of loss of electrons which is greater in the continuous discharge than in the striated one, for along the continuous discharge there are as many positive ions as electrons and thus there is a very considerable loss of electrons due to their recombination with the positive ions. This does not occur to the same extent in the striated discharge as in the Faraday dark spaces which form part of the

striated discharge. There are under certain conditions no positive ions and thus no loss of electrons from recombination. Thus we see that there are certain features in the striated discharge which may under special circumstances compensate for the potential in this type of discharge having to increase beyond the minimum required to produce ionization, and thus cause the discharge to pass in the striated form.

The positive column is often by far the most conspicuous part of the discharge, the thickness of Crookes' dark space, and of the negative glow do not depend on the distance between the cathode and anode in the discharge tube and if this is great practically the whole length of the discharge may consist of the positive column. Thus for example when a spark passes through air at atmospheric pressure the dark space and the negative glow do not extend beyond a fraction of a millimetre, all the rest of the spark is positive column.

In one very interesting form of discharge known as the electrodeless ring discharge the positive column constitutes the whole of the discharge; there is no dark space, and no negative glow. This type of discharge may be produced by pulling a cylindrical tube containing gas at a low pressure inside a solenoid through which rapidly alternating currents such as those produced by discharging a Leyden jar are passing. These alternating currents produce by electromagnetic induction electric forces in the exhausted tubes; the direction of these forces is tangential to circles having their centres along the axis of the solenoid and their planes at right angles to it. Thus the lines of electric force through the rarefied gas form closed circles round which the electrons circulate. No regenerative effect, such as occurs at the cathode in the ordinary type of discharge is required as the electrons are not taken out of the gas. Ionization by electronic-collision alone is thus sufficient to maintain the discharge. The discharge under these circumstances forms a brightly luminous ring which is in general of uniform luminosity. J. J. Thomson has shown that in hydrogen this ring sometimes shows well marked striations, and also that under certain conditions large currents may pass through the gas without showing more than a mere trace of luminosity.

The connection between the potential difference and the spark length has been made the subject of a large number of experiments. The first measurements were made by Lord Kelvin in 1860 (*Collected Papers on Electrostatics and Magnetism*, p. 247); subsequent experiments have been made by Baille (*Ann. de chimie et de physique*, 5, 25, p. 486), Liebig (*Phil. Mag.* [5], 24, p. 106), Paschen (*Wied. Ann.* 37, p. 79), Peace (*Proc. Roy. Soc.*, 1892, 52, p. 99), Orgler (*Ann. der Phys.* 1, p. 159), Strutt (*Phil. Trans.* 193, p. 377), Bouty (*Comptes rendus*, 131, pp. 469, 503), Earhart (*Phil. Mag.* [6], 1, p. 147), Carr (*Phil. Trans.*, 1903), Russell (*Phil. Mag.* [5], 64, p. 237), Hobbs (*Phil. Mag.* [6], 10, p. 617), Kinsley (*Phil. Mag.* [6], 9, 692), Ritter (*Ann. der Phys.* 14, p. 118). The results of their experiments show that for sparks considerably longer than the critical spark length, the relation between the potential difference V and the spark length l may be expressed when the electrodes are large with great accuracy by the linear relation $V=c+blp$, where p is the pressure and c and b are constants depending on the nature of the gas. When the sparks are long the term blp is the most important and the sparking potential is proportional to the spark length. Though there are considerable discrepancies between the results obtained by different observers, these indicate that the production of a long spark between large electrodes in air at atmospheric pressure requires a potential difference of 30,000 volts for each centimetre of spark length. In hydrogen only about half this potential difference is required, in carbonic acid gas the potential difference is about the same as in air, while Ritter's experiments show that in helium only about one-tenth of this potential difference is required. From a previous equation the coefficient of l in the expression for the spark potential is P/λ where P is the potential of the gas and λ the free path of the electron. A very complete account of the various determinations of P is given in K. T. Compton and Mohler's report on Critical Potentials (*Bulletin National Research Council*, U.S.A. Sept. 1924). P is about 16 volts for H_2 and O_2, 17 for N_2 and 25 for H_e. Since experiments on the spark potential give P/λ when P is known, λ can be deduced.

When the electric field is not uniform, as for example when the discharge takes place between spherical electrodes, Russell's experiments show that the discharge takes place as soon as the maximum electric force in the field between the electrodes reaches

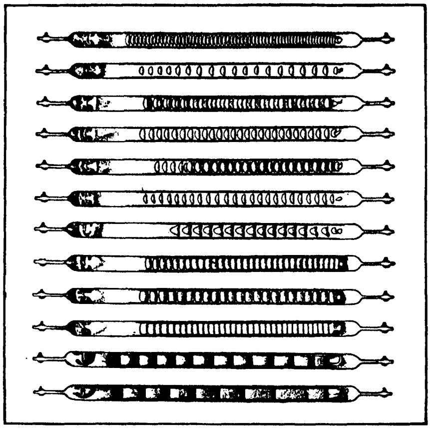

FIG. 13

a definite value, which he found was for air at atmospheric pressure about 38,000 volts per centimetre.

Striated Discharge.—We have already described the general appearance of the discharge through gases at low pressures. (*See* p. 259.) The striated form of discharge is, however, so striking and beautiful that it deserves more detailed consideration. Some forms of this are represented in fig. 13, which is taken from a paper by De la Rue and Müller (*Phil. Trans.*, 1878, Pt. 1). This type of discharge only occurs when the current and the pressure of the gas are between certain limits. It is most beautifully shown when a Wehnelt cathode is used and the current is produced by storage cells, as this allows us to use large currents and to maintain a steady potential difference between the electrodes. The striations are in consequence very bright and steady. The facts which have been established about these striations are as follows: The distance between the bright parts of the striations is greater at low pressures than at high; it depends also upon the diameter of the tube, increasing as the diameter of the tube increases. If the discharge tube is wide at one place and narrow in another the striations will be closer together in the narrow parts than in the wide. The distance between the striations depends on the current through the tube. The relation is not a very simple one, as an increase of current sometimes increases while under other circumstances it decreases the distance between the striations. (*See* Willows, *Proc. Camb. Phil. Soc.* 10. p. 302.) The electric force is not uniform along the striated discharge, but is greater in the bright than in the dark parts of the striation.

An example is shown in fig. 16, due to H. A. Wilson, which shows the distribution of electric force at every place in a striated discharge. In experiments made by J. J. Thomson (*Phil. Mag.*, Oct., 1909), using a Wehnelt cathode, the variations in the electric force were more pronounced than those shown in fig. 12. The electric force in this case changed so greatly that it actually became negative just on the cathode side of the bright part of the striation. Just inside the striation on the anode side it rose to a very high value, then continually diminished towards the bright side of the next striation when it again increased. This distribution of electric force implies that there is great excess of negative elec-

tricity at the bright head of the striation, and a small excess of positive everywhere else. The temperature of the gas is higher in the bright than in the dark parts of the striations. Wood (*Wied. Ann.*, 49, p. 238), who has made a very careful study of the distribution of temperature in a discharge tube, finds that in those tubes the temperature varies in the same way as the electric force, but that this temperature (which it must be remembered is the average temperature of all the molecules and not merely of those which are taking part in the discharge) is by no means high; in no part of the discharge did the temperature in his experiments exceed 100° C.

Aston (*Proc. Roy. Soc.*, 80, p. 45, 1908; 84, p. 531, 1911), has discovered in helium and hydrogen a second dark space close to the cathode of much smaller thickness than the Crookes' dark space; it is especially noticeable in helium. Unlike the Crookes' space the thickness of this does not change with the pressure, but it increases when the current through the tube diminishes.

Distribution of Luminosity in the Discharge.—As will be gathered from the preceding account the amount of visible light given out by the discharge varies very much from one part to another, although all the parts are traversed by the same current. Though the dark spaces do not emit much visible light they do emit radiation though this is of much smaller wave length than that in the visible part of the spectrum. Again Seeliger and his colleagues have shown that even in the Crookes' dark space some lines due to the gas in the tube may be present even at some distance from the negative glow. The emission of visible light is not a necessary consequence of ionization; we can have ionization without appreciable luminosity and we can also have bright luminosity without ionization. The greater part of the light in the visible part of the discharge seems to arise not from atoms or molecules which have been ionized but from those which have received some energy from electrons which though it is not sufficient to detach an electron from the atom is sufficient to displace the electron to a new position of equilibrium in the atom, and it is the return from the old to the new which is responsible for the emission of light.

The question of luminosity in the discharge is one which is primarily concerned with the mechanism of radiation and is most appropriately considered under spectroscopy.

Short Sparks.—Some very interesting experiments on the potential difference required to produce exceedingly short sparks have been made by Earhart, Hobbs and Kinsley; the length of these sparks was comparable with the wave length of sodium light. With sparks of these lengths it was found that it was possible to get a discharge with less than 330 volts, the minimum potential difference in air. The results of these observers show that there is no diminution in the minimum potential difference required to produce discharge until the spark length gets so small that the average electric force between the electrodes amounts to about one million volts per centimetre. When the force rises to this value a discharge takes place even though the potential difference is much less than 330 volts; in some of Earhart's experiments it was only about 2 volts. This kind of discharge is determined not by the condition that the potential difference should have a given value, but that the electric force should have a given value. Another point in which this discharge differs from the ordinary one is that it is influenced entirely by the nature of the electrodes and not by the nature or pressure of the gas between them, whereas the ordinary discharge is in many cases not affected appreciably by changes in the metal of the electrodes, but is always affected by changes in the pressure and character of the gas between them. Kinsley found that when one of these small sparks passed between the electrodes a kind of metallic bridge was formed between them, so that they were in metallic connection, and that the distance between them had to be considerably increased before the bridge was broken. Almy (*Phil. Mag.*, Sept. 1908), who used very small electrodes, was unable to get a discharge with less than the minimum spark potential even when the spark length was reduced to one-third of the wave length of sodium light. He suggests that the discharges obtained with larger electrodes for smaller voltages are due to the electrodes being dragged together by the electrostatic attraction between them.

Experiments bearing on this point have recently been made by Lilienfeld (*Zeit. f. Phys.* xv., p. 46, 1923); Millikan and Eyring (*Phys. Review*, xxvii., p. 51, 1926); Rother (*Ann. der Phy.* 81, p. 317, 1926); De Bruyne (*Phil. Mag.*, 5 p. 574, 1928); and del Rosario (*Journal Franklin Society* 203, p. 243) who have experimented with very high vacua (at pressures less than 10^{-6} mm.) and with cathodes carefully freed from gas. When the electron force at the cathode is of the order of a million volts per centimetre currents flow from the cathode. Lilienfeld and De Bruyne attribute them to electrons being torn from the metal by the strong electric field, del Rosario to the presence of residual gas. It would seem that even if the electrons could not be dragged out of the metal by the electric force an electric current should be able to pass across a vacuum if the potential difference between the electrodes were very large. For suppose there was a casual electron between the electrodes, this would be driven by the electric field against the anode, the impact would produce Röntgen rays, those falling on the cathode would produce an emission of electrons by the photoelectric effect. If the energy given to the electron by the field were great enough to make the Röntgen rays cause the emission of one or more electrons the discharge would be self-sustained. This effect would depend on the potential difference between the electrodes while the extraction of electrons by the electric force would depend on the electric force at the cathode.

The Arc Discharge.—The discharges we have hitherto considered have been characterized by large potential differences and small currents. If the current through the discharge tube is gradually increased starting from a small value the following stages are passed through: at first, when the current is so small that the cathode is not wholly covered with glow the current density at the cathode and the cathode fall of potential are constant. When the current reaches the value when the cathode is covered with glow both the current density and the cathode fall increase rapidly with the current. When the current density reaches a certain value the appearance suddenly changes, there is a sudden jump in the current density, a large fall in the potential difference at the cathode, the dark space disappears, and the electrodes get very hot. This is the arc discharge. In the arc discharge we get very large currents with comparatively small potential differences. We may get the arc discharge by taking a battery of cells large enough to give a potential difference of 60 to 80 volts, and connecting the cells with two carbon terminals,

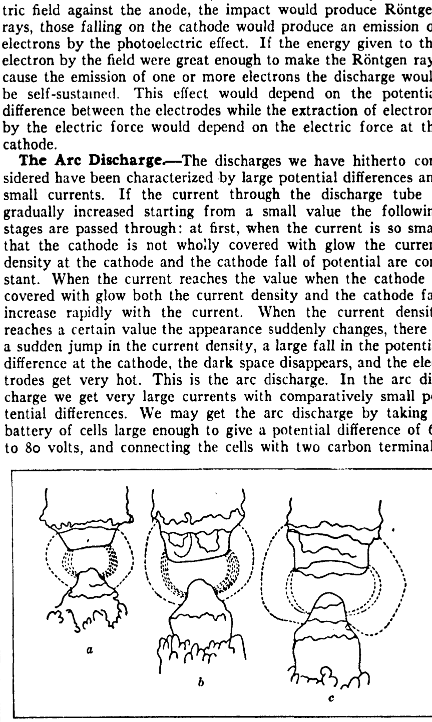

FIG. 14

which are put in contact, so that a current of electricity flows round the circuit. If the terminals, while the current is on, are drawn apart, a bright discharge, which may carry a current of many amperes, passes from one to the other. This arc discharge, as it is called, is characterized by intense heat and by the brilliant luminosity of the terminals. This makes it a powerful source of light. The temperature of the positive terminal is much higher than that of the negative. According to Violle (*Comptes Rendus*, 115, p. 1273) the temperature of the tip of the former is about 3,500° C, and that of the latter 2,700° C. The temperature of the

arc itself he found to be higher than that of either of its terminals. As the arc passes, the positive terminal gets hollowed out into a crater-like shape, but the negative terminal remains pointed. Both terminals lose weight.

The appearance of the terminals is shown in fig. 14, given by Mrs. Ayrton (*Proc. Inst. Elec. Eng.* 28, p. 400); *a, b* represent the terminals when the arc is quiet, and *c* when it is accompanied by a hissing sound. The intrinsic brightness of the positive crater does not increase with an increase in the current; an increased current produces an increase in the area of the luminous crater, but the amount of light given out by each unit of area of luminous surface is unaltered. This indicates that the temperature of the crater is constant; it is probably that at which carbon volatilizes. W. E. Wilson (*Proc. Roy. Soc.* 58, p. 174; 60, p. 377) has shown that at pressures of several atmospheres the intrinsic brightness of the crater is considerably diminished.

The connection between V, the potential difference between the terminals, and l, the length of the arc, is somewhat analogous to that which holds for the spark discharge. Fröhlich (*Electrotech. Zeit.* 4, p. 150) gives for this connection the relation $V=m+nl$, where m and n are constants. Mrs. Ayrton (*The Electric Arc*, chap. iv.) finds that both m and n depend upon the current passing between the terminals, and gives as the relation between V and l, $V=\alpha+\beta l+\gamma+\frac{\delta l}{I}l$, where $\alpha, \beta, \gamma, \delta$ are constants and I the current. With this relation VI is a linear function of I so that the graph representing the relation between Watts and current is a straight line which does not pass through the origin. The relation between current and potential difference was made the subject of a series of experiments by Ayrton (*Electrician*, I., p. 319; xi. p. 418), some of whose results are represented in fig. 15. For

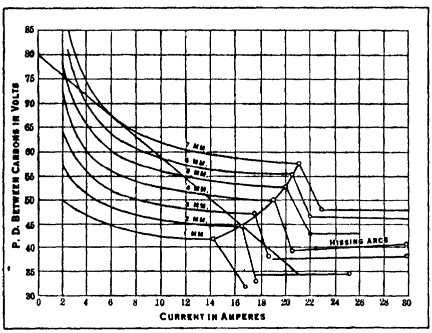

FIG. 15

a quiet arc an increase in current is accompanied by a fall in potential difference, while for the hissing arc the potential difference is independent of the current.

Many determinations have been made of the constants for different electrodes and different gases. Tables I. and II. give some idea of their values. Table I. refers to the values for different electrodes in air at atmospheric pressure and Table II. to carbon electrodes in different gases.

TABLE I.

Electrode	α	β	γ	δ		Observer
Carbon	38·88	2·0	16·64	10·54	Cooled	Ayrton
	39·6	1·7	15·5	11·5	elec-	Duddell
	45·75	3·3	35·7	19·31	trodes	Palmer and Wäyrynen
Copper	26·61	2·22	32·49	18·6	Cooled	Palmer and Wäyrynen
	15·24	10·69	21·38	3·02	elec-	Guye and Zebrikoff
Silver	19·01	11·36	14·19	3·64	trodes	,, ,, ,,
Iron	15·01	9·44	15·73	2·52		,, ,, ,,

TABLE II.

Gas	α	β	γ	δ	Observer
Air (stagnant)	35·7	3·0	11·46	1·8	Kohn and Guckel
Air (current)	44·1	2·6	17·8	1·8	,, ,, ,,
Argon	24·8	0·9	10·2	0·0	,, ,, ,,
CO_2	44·5	1·7	18·2	8·7	,, ,, ,,
N_2	48·2	2·6	23·3	5·3	,, ,, ,,

The values of α β δ change only slowly with the pressure; γ changes more rapidly.

According to Kohn and Guckel, the anode fall of potential is $\frac{4}{5}\alpha+\frac{\gamma}{2i}$ the cathode fall $\frac{\alpha}{5}+\frac{\gamma}{2i}$ and the potential gradient in the arc $\beta+\frac{\delta}{i}$. It is shown that when the discharge is passing through a gas it will not be stable unless

$$\frac{dV}{d^3}+R>0$$

where R is the resistance of the leads.

Applying this to Ayrton's relation between V and I we find that the smallest current which will give a stable arc is given by

$$I_{\min}=\sqrt{\frac{\gamma+\delta l}{R}}$$

the maximum resistance that will give a stable arc is

$$R=\frac{\gamma+\delta l}{I^2}.$$

Nottingham (*Phys. Review* 28, p. 764, 1926) has shown that the relation $V=A-B/l^n$ where A and B are quantities which depend upon the length of the arc and the pressure, is very closely satisfied provided the anode is at a very high temperature. The value of n depends upon the boiling point of the metal of the anode; if this in absolute measures is T

$$n=2{\cdot}62\times10^{-4}T$$

for copper $n=0{\cdot}67$.

In comparing values in Tables I. and II., it is important to remember that Lecher has shown that with Fe or Pt terminals the arc discharge is intermittent. Arons has shown that this is also the case with Hg terminals, but no intermittence has been detected with terminals of C, Ag or Cu. The preceding measurements refer to mean potentials, and no conclusions as to the actual potential differences at any time can be drawn when the discharge is discontinuous, unless we know the law of discontinuity. The ease

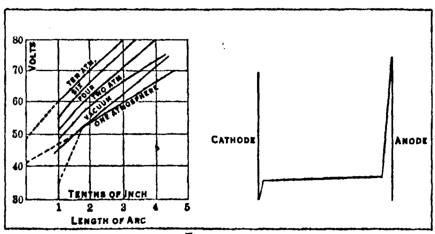

FIG. 16 & 17

with which an arc is sustained depends greatly on the nature of the electrodes; when they are brass, zinc, cadmium, or magnesium it is exceedingly difficult to get the arc.

The potential difference between the terminals is affected by the pressure of the gas. The most extensive series of experiments on that point is that made by Duncan, Rowland and Tod (*Electrician*, 31, p. 60), whose results are represented in fig. 16. We see from these curves that for very short arcs the potential difference increases continuously with the pressure, but for longer ones there is a critical pressure at which the potential difference

is a minimum, and that this critical pressure seems to increase with the length of arc.

The nature of the gas also affects the potential difference. The magnitude of this effect may be gathered from the following values given by Arons (*Ann. der Phys.* 1, p. 700) for the potential difference required to produce an arc 1·5 mm. long, carrying a current of 4·5 amperes, between terminals of different metals in air and pure nitrogen.

Terminal	Air	Nitrogen	Terminal	Air	Nitrogen
Ag . .	21	?	Pt . .	36	30
Zn . .	23	21	Al . .	39	27
Cd . .	25	21	Pb . .	..	18
Cu . .	27	30	Mg . .	..	22
Fe . .	29	20			

Thus, with the discharge for an arc of given length and current, the nature of the terminals is the most important factor in determining the potential difference. The effects produced by the pressure and nature of the surrounding gas, although quite appreciable, are not of so much importance, while in the spark discharge the nature of the terminals is of small importance, compared with the nature and pressure of the gas.

The potential gradient in the arc is very far from being uniform. With carbon terminals Luggin (*Wien. Ber.* 98, p. 1192) found that, with a current of 15 amperes, there was a fall of potential of 33·7 close to the anode, and one 8·7 close to the cathode, so that the curve representing the distribution of potential between the terminals would be somewhat like that shown in fig. 17, though the change of potential at the electrodes is much more abrupt than that represented in the figure. We have seen that a somewhat analogous distribution of potential holds in the case of conduction through flames, though in that case the greatest drop of potential is in general at the cathode and not at the anode. The difference between the changes of potential at the anode and cathode is not so large with Fe and Cu terminals as with carbon ones; with mercury terminals, Arons (*Wied. Ann.* 58, p. 73) found the anode fall to be 7·4 volts, the cathode fall 5·4 volts.

The case of the arc when the cathode is a pool of mercury and the anode a metal wire placed in a vessel from which the air has been exhausted is one which has attracted much attention, and important investigations on this point have been made by Hewitt (*Electrician,* 52, p. 447); Wills (*Electrician,* 54, p. 26); Stark, Retschinsky and Schnaposnikoff (*Ann. der Phys.* 18, p. 213); and Pollak (*Ann. der Phys.* 19, p. 217). In this arrangement the mercury is vaporized by the heat, and the discharge which passes through the mercury vapour gives an exceedingly bright light, which has been largely used for lighting factories, etc. The arrangement can also be used as a rectifier, for a current will only pass through it when the mercury pool is the cathode. Thus if such a lamp is connected with an alternating current circuit, it lets through the current in one direction and stops that in the other, thus furnishing a current which is always in one direction.

The Singing Arc.—Unlamped vibrations of a circuit containing self-induction and capacity can be obtained by inserting in the oscillating circuit an arc discharge produced by a constant potential difference between carbon electrodes. The energy required to maintain these vibrations comes from the arc and the action is as follows. When the current from the oscillating circuit passes through the arc in the same direction as the arc current the current through the arc is increased. If i is the current through the arc, I that round the oscillating circuit, the potential difference between the terminals of the arc is increased by $\frac{dV}{di}I$ when the oscillating current goes through it. In the arc discharge if dV/di is negative so that the passage of I through the arc reduces the potential difference between its terminals, this reduction is equal to $-IdV/di$. The effect of this on the oscillating circuit is the same as if an electromotive force equal to this reduction acted on the oscillating circuit in the direction tending to increase the current; this communicates energy to the oscillating circuit at the rate $-I^2dv/de$. The rate at which this circuit loses energy due to its resistance is rI^2 where r is its resistance, hence if

$$-I^2\frac{dV}{di} > rI^2$$

or

$$-\frac{dV}{di} > r$$

the circuit will get enough energy from the arc to balance its losses and the oscillations will be maintained. This condition was given by Duddell (*Electrician* 46. pp. 269–310, 1900) who made very important investigations on this subject. When the magnitude of the currents in the oscillating circuit are small compared with the arc current, they will not be able to produce great changes in the potential difference between the terminals of the arc. When however the oscillating currents approach in magnitude the arc current they will quench the arc when they flow in the opposite direction to these currents. The stoppage of the current will produce a great increase in the potential difference between the arc terminals, this will be communicated to the plates of the condenser and in this may start vibrations of great amplitude and energy.

Theory of the Arc Discharge.—An incandescent body such as a piece of carbon, even when at a temperature far below that of the terminals in an arc, emits electrons at a rate corresponding to a current of the order of 1 ampere per square centimetre of incandescent surface, and as the rate of increase of emission with the temperature is very rapid, it is probably at the rate of many amperes per square centimetre at the temperature of the negative carbon in the arc. If then a piece of carbon were maintained at this temperature by some external means, and used as a cathode, a current could be sent from it to another electrode whether the second electrode were cold or hot. If, however, these electrons did not produce other ions either by collision with the gas through which they move or with the anode, the spaces between cathode and anode would have a negative charge, which through the space charge effect would tend to stop the electrons leaving the cathode and would require a large potential difference between anode and cathode to produce any considerable current. If, however, there is ionization either in the gas or at the anode, the positive ions will diffuse into the region of the discharge until they are sensibly equal in number to the negative ions. When this is the case the back electromotive force is destroyed and the same potential difference will carry a much larger current. The arc discharge may be regarded as analogous to the discharge between incandescent terminals, the only difference being that in the arc the terminals are maintained in the state of incandescence by the current and not by external means. On this view the cathode is bombarded by positive ions which heat it to such a temperature that electrons sufficient to carry the current are emitted by it. These electrons bombard the anode and keep it incandescent. They ionize also, either directly by collision or indirectly by heating the anode, the gas and vapour of the metal of which the anode is made, and produce in this way the supply of positive ions which keep the cathode hot.

There is still considerable uncertainty as to how the ionization of the gas in the arc discharge is produced. In some cases such as mercury vapour, neon and helium arcs have been observed when the potential difference between the electrodes is less than the ionizing potential of the gas. This has led to various suggestions, *e.g.,* that the ionization is not due to a single collision but to the accumulation of the effects of two or more consecutive ones, it has also been suggested that the ionization is not due directly to collisions but is a thermal dissociation produced by the high temperature of the gas. It ought however in this connection to be remembered that the potential difference between the electrodes is not always the greatest potential difference in the field, for an extreme instance of this is an experiment made by J. J. Thomson (*Phil. Mag.* 18, p. 449, 1909) when a fully developed discharge with cathode fall of potential, dark space, and striations, was produced between two electrodes in metallic connection.

Though the potential fall at the cathode in the arc discharge is much smaller than the normal cathode fall in the glow discharge

it is very much more abrupt. We have no direct measurements of the thickness of the larger in the arc next the cathode in which the cathode potential fall is developed, we know however that it is exceedingly small, possibly at atmospheric pressure of the order of 10^{-5} centimetres. The smaller it is the greater the electric force at the cathode; if it were 10^{-5} cm. this force would be of the order of a million volts per centimetre. Langmuir has suggested that under such forces electrons may be extracted from the cathode and that this might supplement or even replace the thermionic emission. We have seen in this article that there is some evidence from other sources of the extraction of electrons from metals by forces comparable with a million volts per centimetre. This may help us to understand how it is that from a metal like mercury with a low boiling point there may be an emission of electrons so large that if it were thermionic in origin the temperature of the metal must be very much higher than the boiling point.

Discharge from a Point.—A very interesting case of electric discharge is that between a sharply pointed electrode, such as a needle, and a metal surface of considerable area. At atmospheric pressures the luminosity is confined to the immediate neighbourhood of the point. If the sign of the potential of the point does not change, the discharge is carried by ions of one sign—that of the charge on the pointed electrode. The velocity of these ions under a given potential gradient has been measured by Chattock (*Phil. Mag.* 32, p. 285), and found to agree with that of the ions produced by Röntgen or uranium radiation, while Townsend (*Phil. Trans.* 195, p. 259) has shown that the charge on these ions is the same as that on the ions streaming from the point. If the pointed electrode be placed at right angles to a metal plane serving as the other electrode, the discharge takes place when, for a given distance of the point from the plane, the potential difference between the electrodes exceeds a definite value depending upon the pressure and nature of the gas through which the discharge passes; its value also depends upon whether, beginning with a small potential difference, we gradually increase it until discharge commences, or, beginning with a large potential difference, we decrease it until the discharge stops. The value found by the latter method is less than that by the former.

According to Chattock's measurements the potential difference V for discharge between the point and the plate is given by the linear relation $V=a+bl$, where l is the distance of the point from the plate and a and b are constants. From v. Obermayer's (*Wien. Ber.* 100, 2, p. 127) experiments, in which the distance l was greater than in Chattock's, it would seem that the potential for larger distances does not increase quite so rapidly with l as is indicated by Chattock's relation. The potential required to produce this discharge is much less than that required to produce a spark of length l between parallel plates; thus from Chattock's experiments to produce the point discharge when $l=\cdot 5$ cm. in air at atmospheric pressure requires a potential difference of about 3,800 volts when the pointed electrode is positive, while to produce a spark at the same distance between plane electrodes would require a potential difference of about 15,000 volts. Chattock showed that with the same pointed electrode the value of the electric intensity at the point was the same whatever the distance of the point from the plane. The value of the electric intensity depended upon the sharpness of the point.

Determinations of the electric force and potential difference required to produce discharge from pointed electrodes have been made by Chattock (*Phil. Mag.* 20, p. 273, 1910); Chattock and Tyndall (*Phil. Mag.* 120, p. 285, 1910); Edmunds (*Phil. Mag.* 28. p. 234, 1914); and Zeleny (*Phys. Review* 3, p. 69, 1914; 16. 102. 1920) who has made a very interesting series of experiments on this subject using not only metallic points, but also points made of minute drops of water, glycerine, and methyl alcohol. He found but little difference between the electric force required to spark from a metal point and that from a metallic one of the same radius. He obtained as an empirical formula for the connection between f the electric force at the point, and the radius of the point and p the pressure of the gas

$$fV=Apr+B\sqrt{pr}$$

a form which had been suggested previously by Edmunds. For air, Zeleny finds $A=0{\cdot}955$; $B=5{\cdot}6$; f being measured in electrostatic units, r in centimetres, and p in centimetres of mercury. The potential difference V in volts required to produce a spark to a plate at a given distance from the point, is given by

$$V=a\sqrt{r}+b$$

when a is a quantity depending on the pressure. For air b is 340 volts, agreeing very closely with the minimum potential required to produce a spark in that gas. He found too that the lag in time between the application of the forces and the passage of the spark was especially pronounced in liquid electrodes, he attributes this lag to a non-conducting layer, perhaps of gas over the surface of the liquid which has to be pierced before the spark can pass. Warburg (*Wied. Ann.* 67, 69, 1899, showed that the current due to a potential difference V is proportional to v $(V-U)$ where U is the potential required to start the spark.

The value of the electric intensity at the pointed electrode is much greater than its value at a plane electrode for long sparks; but we must remember that at a distance from a pointed electrode equal to a small multiple of the radius of curvature of its extremity the electric intensity falls very far below that required to produce discharge in a uniform field, so that the discharge from a pointed electrode ought to be compared with a spark whose length is comparable with the radius of curvature of the point. For such short sparks the electric intensity is very high. The electric intensity required to produce the discharge from a gas diminishes as the pressure of the gas diminishes, but not nearly so rapidly as the electric intensity for long sparks. Here again the discharge from a point is comparable with short sparks, which, as we have seen, are much less sensitive to pressure changes than longer ones. The minimum potential at which the electricity streams from the point does not depend upon the material of which the point is made; it varies, however, considerably with the nature of the gas. The following are the results of some experiments on this point. Those in the first two columns are due to Röntgen, those in the third and fourth to Precht:—

Gas	Discharge potential. Point +		Pressure 760	
	Pressure 205	Pressure 110	Point +	Point −
	Volts	Volts	Volts	Volts
H_2	1,296	1,174	2,125	1,550
O_2	2,402	1,975	2,800	2,350
CO	2,634	2,100	..	..
CH_4	2,777	2,317	..	..
NO	3,188	2,543	..	..
CO_2	3,287	2,655	3,475	2,100
N_2	..	..	2,600	2,000
Air	..	..	2,750	2,050

We see from this table that in the case of the discharge from a positively electrified point the greater the molecular weight of the gas the greater the potential required for discharge. Röntgen concluded from his experiments that the discharging potential from a positive point in different gases at the same pressure varies inversely as the mean free path of the molecules of the gas. In the same gas, however, at different pressures the discharging potential does not vary so quickly with the pressure as does the mean free path. In Precht's experiments, in which different gases were used, the variations in the discharging potential are not so great as the variations in the mean free path of the gases.

The current of electrified air flowing from the point when the electricity is escaping—the well-known "electrical wind"—is accompanied by a reaction on the point which tends to drive it backwards. This reaction has been measured by Arrhenius (*Wied. Ann.* 63, p. 305), who finds that when positive electricity is escaping from a point in air the reaction on the point for a given current varies inversely as the pressure of the gas, and for different gases (air, hydrogen and carbonic acid) inversely as the square root of the molecular weight of the gas. The reaction when negative electricity is escaping is much less. The proportion between

the reactions for positive and negative currents depends on the pressure of the gas. Thus for equal positive and negative currents in air at a pressure of 70 cm. the reaction for a positive point was 1·9 times that of a negative one, at 40 cm. pressure 2·6 times, at 20 cm. pressure 3·2 times, at 10·3 cm. pressure 7 times, and at 5·1 cm. pressure 15 times the reaction for the negative point. Investigation shows that the reaction should be proportional to the quotient of the current by the velocity acquired by an ion under unit potential gradient. Now this velocity is inversely proportional to the pressure, so that the reaction should on this view be directly proportional to the pressure. This agrees with Arrhenius' results when the point is positive.

Again, the velocities of an ion in hydrogen, air and carbonic acid at the same pressure are approximately inversely proportional to the square roots of their molecular weights, so that the reaction should be directly proportional to this quantity. This also agrees with Arrhenius' results for the discharge from a positive point. The velocity of the negative ion is greater than that of a positive one under the same potential gradient, so that the reaction for the negative point should be less than that for a positive one, but the excess of the positive reaction over the negative is much greater than that of the velocity of the negative ion over the velocity of the positive. There is, however, reason to believe that a considerable condensation takes place around the negative ion as a nucleus after it is formed, so that the velocity of the negative ion under a given potential gradient will be greater immediately after the ion is formed than when it has existed for some time. The measurements which have been made of the velocities of the ions relate to those which have been some time in existence, but a large part of the reaction will be due to the newly-formed ions moving with a greater velocity, and thus giving a smaller reaction than that calculated from the observed velocity.

With a given potential difference between the point and the neighbouring conductor the current issuing from the point is greater when the point is negative than when it is positive, except in oxygen, when it is less. Warburg (*Sitz. Akad. d. Wissensch. zu Berlin*, 1899, 50, p. 770) has shown that the addition of a small quantity of oxygen to nitrogen produces a great diminution in the current from a negative point, but has very little effect on the discharge from a positive point. Thus the removal of a trace of oxygen made a leak from a negative point 50 times what it was before. Experiments with hydrogen and helium showed that impurities in these gases had a great effect on the current when the point was negative, and but little when it was positive. This suggests that the impurities, by condensing round the electrons as nuclei, seriously diminish their velocity.

If a point is charged up to a high and rapidly alternating potential, such as can be produced by the electric oscillations started when a Leyden jar is discharged, then in hydrogen, nitrogen, ammonia and carbonic acid gas a conductor placed in the neighbourhood of the point gets a negative charge, while in air and oxygen it gets a positive one. There are two considerations which are of importance in connection with this effect. The first is the velocity of the ions in the electric field, and the second the ease with which the ions can give up their charges to the metal point. The greater velocity of the negative ions would, if the potential were rapidly alternating, cause an excess of negative ions to be left in the surrounding gas. This is the case in hydrogen. If, however, the metal had a much greater tendency to unite with negative than with positive ions, such as we should expect to be the case in oxygen, this would act in the opposite direction, and tend to leave an excess of positive ions in the gas.

The Characteristic Curve for Discharge Through Gases.—When a current of electricity passes through a metallic conductor the relation between the current and the potential difference is the exceedingly simple one expressed by Ohm's law; the current is proportional to the potential difference. When the current passes through a gas there is no such simple relation. Thus we have already mentioned cases where the current increased as the potential increased although not in the same proportion, while as we have seen in certain stages of the arc discharge the potential difference diminishes as the current increases. Thus the problem of finding the current which a given battery will produce when part of the circuit consists of a gas discharge is much more complicated than when the circuit consists entirely of metallic conductors. If, however, we measure the potential difference between the electrodes in the gas when different currents are sent through it, we can plot a curve, called the "characteristic curve," whose ordinates are the potential differences between the electrodes in the gas and the abscissae the corresponding currents. By the aid of this curve we can calculate the current produced when a given battery is connected up to the gas by leads of known resistance.

For let E_0 be the electromotive force of the battery, R the resistance of the leads, i the current, the potential difference between the terms in the gas will be E_0-Ri. Let ABC (fig. 18) be the "characteristic curve," the ordinates being the potential difference between the terminals in the gas, and the abscissae the current. Draw the line LM whose equation is $E=E_0-Ri$, then the points where this line cuts the characteristic curves will give possible values of i and E, the current through the discharge tube and the potential difference between the terminals. Some of these points may, however, correspond to an unstable position and be impossible to realize. The following method gives us a criterion by which we can distinguish the stable from the unstable positions. If the current is increased by δi, the electromotive force which has to be overcome by the battery is $R\delta i+\frac{dE}{di}\delta i$. If $R+dE/di$ is positive there will be an unbalanced electromotive force round the circuit tending to stop the current. Thus the increase in the current will be stopped and the condition will be a stable one. If, however, $R+dE/di$ is negative there will be an unbalanced electromotive force tending to increase the current still further; thus the current will go on increasing and the condition will be unstable. Thus for stability $R+dE/di$ must be positive, a condition first given by Kaufmann (*Ann. der Phys.* 11, p. 158). The geometrical interpretation of this condition is that the straight line LM must, at the point where it cuts the characteristic curve, be steeper than the tangent to characteristic curve. Thus of the points ABC where the line cuts the curve in fig. 18, A and C correspond to stable states and B to an unstable one. The state of things represented by a point P on the characteristic curve when the slope is downward cannot be stable unless there is in the external circuit a resistance greater than that represented by the tangent of the inclination of the tangent to the curve at P to the horizontal axis.

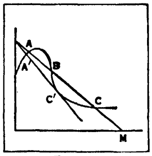

FIG. 18

If we keep the external electromotive force the same and gradually increase the resistance in the leads, the line LM will becаme steeper and steeper. C will move to the left so that the current will diminish; when the line gets so steep that it touches the curve at C′, any further increase in the resistance will produce an abrupt change in the current; for now the state of things represented by a point near A′ is the only stable state. Thus if the BC part of the curve corresponded to a luminous discharge and the A part to a dark discharge, we see that if the electromotive force is kept constant there is a minimum value of the current for the luminous discharge. If the current is reduced below this value, the discharge ceases to be luminous, and there is an abrupt diminution in the current.

Cathode Rays.—When the gas in the discharge tube is at a very low pressure some remarkable phenomena occur in the neighbourhood of the cathode. These seem to have been first observed by Plücker (*Pogg. Ann.* 107, p. 77; 116, p. 45) who noticed on the walls of the glass tube near the cathode a greenish phosphorescence, which he regarded as due to rays proceeding from the cathode, striking against the sides of the tube, and then travelling back to the cathode. He found that the action of a magnet on these rays was not the same as the action on the part of the discharge near the positive electrode. Hittorf (*Pogg. Ann.* 136, p. 8) showed that the agent producing the phosphorescence was intercepted by a solid, whether conductor or insulator,

placed between the cathode and the sides of the tube. He regarded the phosphorescence as caused by a motion starting from the cathode and travelling in straight lines through the gas. Goldstein (*Monat. der Berl. Akad.*, 1876, p. 24) confirmed this discovery of Hittorf's, and further showed that a distinct, though not very sharp, shadow is cast by a small object placed near a large plane cathode. This is a proof that the rays producing the phosphorescence must be emitted almost normally from the cathode, and not, like the rays of light from a luminous surface, in all directions, for such rays would not produce a perceptible shadow if a small body were placed near the plane. Goldstein regarded the phosphorescence as due to waves in the ether, for whose propagation the gas was not necessary. Crookes (*Phil. Trans.*, 1879, pt. i. p. 135; pt. ii. pp. 587, 661), who made many remarkable researches in this subject, took a different view. He regarded the rays as streams of negatively electrified particles projected normally from the cathode with great velocity, and, when the pressure is sufficiently low, reaching the sides of the tube, and by their impact producing phosphorescence and heat. The rays on this view are deflected by a magnet, because a magnet exerts a force on a charged moving body.

These rays striking against glass make it phosphorescent. The colour of the phosphorescence depends on the kind of glass; thus the light from soda glass is a yellowish green, and that from lead glass blue. Many other bodies phosphoresce when exposed to these rays, and in particular the phosphorescence of some gems, such as rubies and diamonds, is exceedingly vivid. The spectrum of the phosphorescent light is generally continuous, but Crookes showed that the phosphorescence of some of the rare earths, such as yttrium, gives a spectrum of bright bands, and he founded on this fact a spectroscopic method of great importance. Goldstein (*Wied. Ann.* 54, p. 371) discovered that the haloid salts of the alkali metals change colour under the rays, sodium chloride, for example, becoming violet. The coloration is a surface one, and has been traced by E. Wiedemann and Schmidt (*Wied. Ann.* 54, p. 618) to the formation of a subchloride. Chlorides of tin, mercury and lead also change colour in the same way. E. Wiedemann (*Wied. Ann.* 56, p. 201) discovered another remarkable effect, which he called thermo-luminescence; he found that many bodies after being exposed to the cathode rays possess for some time the power of becoming luminous when their temperature is raised to a point far below that at which they become luminous in the normal state.

Substances belonging to the class called by van 't Hoff solid solutions exhibit this property of thermo-luminescence to a remarkable extent. They are formed when two salts, one greatly in excess of the other, are simultaneously precipitated from a solution. A trace of $MnSO_4$ in $CaSO_4$ shows very brilliant thermo-luminescence. The impact of cathode rays produces after a time perceptible changes in the glass. Crookes (*Phil. Trans.* pt. ii. 1879, p. 645) found that after glass has been phosphorescing for some time under the cathode rays it seems to get tired, and the phosphorescence is not so bright as it was initially. Thus, for example, when the shadow of a Maltese cross is thrown on the walls of the tube as in fig. 19, if after the discharge has been going on for some time the cross is shaken down or a new cathode used whose line of fire does not cut the cross, the pattern of the cross will still be seen on the glass, but it will now be brighter instead of darker than the surrounding portion. The portions shielded by the cross, not being tired by being made to phosphoresce for a long time, respond more vigorously to the stimulus than those portions which have not been protected.

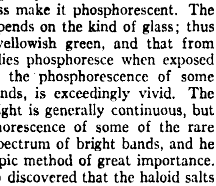

FIG. 19

Skinner (*Proc. Camb. Phil. Soc.* ix. p. 371) and Thomson found on the glass which had been exposed to the rays gelatinous filaments, apparently silica, resulting from the reduction of the glass. A reducing action was also noticed by Villard (*Journ. de phys.* 3, viii. p. 140) and Wehnelt (*Wied. Ann.* 67, p. 421). It can be well shown by letting the rays fall on a plate of oxidized copper, when the part struck by the rays will become bright. The rays heat bodies on which they fall, and if they are concentrated by using as a cathode a portion of a spherical surface, the heat at the centre becomes so great that a piece of platinum wire can be melted or a diamond charred. Measurements of the heating effects of the rays have been made by Thomson (*Phil. Mag.* [5], 44, p. 293) and Cady (*Ann. der Phys.* 1, p. 678). Crookes (*Phil. Trans.*, 1879, pt. i. p. 152) showed that a vane mounted as in a radiometer is set in rotation by the rays, the direction of the rotation being the same as would be produced by a stream of particles proceeding from the cathode. The movement is not due to the momentum imparted to the vanes by the rays, but to the difference in temperature between the sides of the vanes, the rays making the side against which they strike hotter than the other.

Effect of a Magnet.—The rays are deflected by a magnet, so that the distribution of phosphorescence over the glass and the shape and position of the shadows cast by bodies in the tube are altered by the proximity of a magnet. The laws of magnetic deflection of these rays have been investigated by Plücker (*Pogg. Ann.* 103, p. 88), Hittorf (*Pogg. Ann.* 136, p. 213), Crookes (*Phil. Trans.*, 1879, pt. 1, p. 557), and Schuster (*Proc. Roy. Soc.* 47, p. 526). The deflection is the same as that of negatively electrified particles travelling along the path of the rays. Such particles would in a magnetic field be acted on by a force at right angles to the direction of motion of the particle and also to the magnetic force, the magnitude of the force being proportional to the product of the velocity of the particle, the magnetic force, and the sine of the angle between these vectors. In this case we have seen that if the particle is not acted on by an electrostatic field, the path in a uniform magnetic field is a spiral, which, if the magnetic force is at right angles to the direction of projection of the particle, becomes a circle in the plane at right angles to the magnetic force, the radius being mv/He, where m, v, e are respectively the mass, velocity and charge on the particle, and H is the magnetic force. The smaller the difference of potential between the electrodes of the discharge tube the greater the deflection produced by a magnetic field of given strength, and as the difference of potential rapidly increases with diminution of pressure, after a certain pressure has been passed, the higher the exhaustion of the tube the less the magnetic deflection of the rays.

Birkeland (*Comptes rendus*, 1896, p. 492) has shown that when the discharge is from an induction coil the cathode rays produced in the tube at any one time are not equally deflected by a magnet, but that a narrow patch of phosphorescence when deflected by a magnet is split up into several distinct patches, giving rise to what Birkeland calls the "magnetic spectrum." Strutt (Lord Rayleigh) (*Phil. Mag.* 48, p. 478) has shown that this magnetic spectrum does not occur if the discharge of a large number of cells is employed instead of the coil. Thomson (*Proc. Camb. Phil. Soc.* 9, p. 243) has shown that if the potential difference between the electrodes is kept the same the magnetic deflection is independent of the nature of the gas filling the discharge tube; this was tested with gases so different as air, hydrogen, carbonic acid and methyl iodide.

Charge of Negative Electricity Carried by Cathode Rays.—We have seen that the rays are deflected by a magnet, as if they were particles charged with negative electricity. Perrin (*Comptes rendus*, 121, p. 1130) showed by direct experiment that a stream of negative electricity is associated with the rays. A modification made by Thomson of Perrin's experiment is sketched in fig. 20 (*Phil. Mag.* 48, p. 478).

The rays start from the cathode A, and pass through a slit in a solid brass rod B fitting tightly into the neck of the tube. This rod is connected with earth and used as the anode. The rays after passing through the slit travel through the vessel C. D and E are two insulated metal cylinders insulated from each other, and each having a slit cut in its face so as to enable the rays to pass into the inside of the inner cylinder, which is connected with an electrometer, the outer cylinder being connected with the earth. The two cylinders are placed on the far side of the vessel, but

out of the direct line of fire of the rays. When the rays go straight through the slit there is only a very small negative charge communicated to the inner cylinder, but when they are deflected by a magnet so that the phosphorescent patch falls on the slit in the outer cylinder the inner cylinder receives a very large negative charge, the increase coinciding very sharply with the appearance of the phosphorescent patch on the slit. When the patch is so much deflected by the magnet that it falls below the slit, the negative charge in the cylinder again disappears. This experiment shows that the cathode rays are accompanied by a stream of negative electrification.

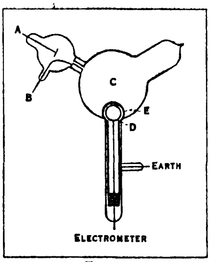

FIG. 20

The same apparatus can be used to show that the passage of cathode rays through a gas makes it a conductor of electricity. For if the induction coil is kept running and a stream of the rays kept steadily going into the inner cylinder, the potential of the inner cylinder reaches a definite negative value below which it does not fall, however long the rays may be kept going. The cylinder reaches a steady state in which the gain of negative electricity from the cathode rays is equal to the loss by leakage through the conducting gas, the conductivity being produced by the passage of the rays through it. If the inner cylinder is charged up initially with a greater negative charge than corresponds to the steady state, on turning the rays on to the cylinder the negative charge will decrease and not increase until it reaches the steady state. The conductivity produced by the passage of cathode rays through a gas diminishes rapidly with the pressure. When rays pass through a gas at a low pressure, they are deflected by an electric field; when the pressure of the gas is higher the conductivity it acquires when the cathode rays pass through it is so large that the potential gradient cannot reach a sufficiently high value to produce an appreciable deflection.

Thus the cathode rays carry a charge of negative electricity; the experiment described on page 252 (fig. 9) shows that they are deflected by an electric field as if they were negatively electrified, and are acted on by a magnetic force in just the way this force would act on a negatively electrified body moving along the path of the rays. There is therefore every reason for believing that they are charges of negative electricity in rapid motion. By measuring the deflection produced by magnetic and electric fields we can determine the velocity with which these particles moved and the ratio of the mass of the particle to the charge carried by it.

We may conclude from the experiments that the value of $\frac{m}{e}$ for the particles constituting the cathode rays is of the order $1/1{\cdot}7\times10^7$, and we have seen that m/e has the same value in all the other cases of negative ions in a gas at low pressure for which it has been measured—viz., for the ions produced when ultra-violet light falls on a metal plate, or when an incandescent carbon filament is surrounded by a gas at a low pressure, and for the β particles given out by radio-active bodies. We have also seen that the value of the charge on the gaseous ion, in all cases in which it has been measured—viz., the ions produced by Röntgen and uranium radiation, by ultra-violet light, and by the discharge of electrification from a point—is the same in magnitude as the charge carried by the hydrogen atom in the electrolysis of solutions. The mass of the hydrogen alone is, however, 10^{-4} times this charge, while the mass of the carriers of negative electrification is only $1/1{\cdot}7\times10^7$ times the charge; hence the mass of the carriers of the negative electrification is only $\frac{1}{1,700}$ of the mass of the hydrogen atom. We are thus, by the study of the electric discharge, forced to recognize the existence of masses very much smaller than the smallest mass hitherto recognized.

Direct determinations of the velocity of the cathode rays have been made by J. J. Thomson (*Phil. Mag.* 38, p. 358), who measured the interval between the appearance of phosphorescence on two pieces of glass placed at a known distance apart, and by Maiorana (*Nuovo Cimento*, 4, 6, p. 336) and Battelli and Stefanini (*Phys. Zeit.* 1, p. 51), who measured the interval between the arrival of the negative charge carried by the rays at two places separated by a known distance. The values of the velocity got in this way are much smaller than the values got by the indirect methods previously described: thus J. J. Thomson at a fairly high pressure found the velocity to be 2×10^7 cm./sec. Maiorana found values ranging between 10^7 and 6×10^7 cm./sec., and Battelli and Stefanini values ranging from 6×10^6 to $1{\cdot}2\times10^7$. In these methods it is very difficult to eliminate the effect of the interval which elapses between the arrival of the rays and the attainment by the means of detection, such as the phosphorescence of the glass or the deflection of the electrometer, of sufficient intensity to affect the senses.

New light has been thrown on the nature of the cathode rays by experiments made by G. P. Thomson (*Proc. Roy. Soc.* A. 117, p. 600; 119, p. 65) and others by Davisson and Germer (*Phys. Review*, 30, p. 705, 1927), G. P. Thomson found that when a thin pencil of cathode rays is sent through an exceedingly thin film of metal or celluloid and then received on a photographic plate the image of the central spot is surrounded by a series of concentric rings, the radii of the rings are in the same ratio as the radii of rings formed when a pencil of Röntgen rays passes through the metal. The molecules of the metal form a crystalline grating and the rings formed by the Röntgen rays are due to the diffraction of the waves of which the rays consist by the grating. Thomson used several metals, gold, silver, platinum and aluminium and found that for each of these the rings formed by the cathode rays followed the same law as the Röntgen ray rings. That the rings formed by the cathode rays were due to the impact of the electrons against the photographic plate and not to secondary Röntgen rays produced by the impact of the electrons against the metal, was proved by the fact that they were deflected by a magnet placed near the photographic plate and far away from the thin film. The electronic waves are of extremely high frequency, never less than $1{\cdot}2\times10^{20}$, a frequency only equalled by that of the hardest γ rays. The wave length of these waves depends upon the velocity of the electron, varying inversely at this velocity. The connection between the velocity u and the wave length λ is expressed by the relation

$$\lambda u = 7{\cdot}5\sqrt{\left(1-\frac{u^2}{c^2}\right)}.$$

Thus when the velocity of the cathode ray is 10^{10} the wave length of the waves which accompany it is 7×10^{-10}. These experiments show that a moving electron cannot be regarded as merely a moving point charge of negative electricity; it includes in addition a train of waves whose wave length varies inversely as the velocity of the electron, when these waves are deflected, *e.g.*, by diffraction the electron follows the waves. Thus the waves may be regarded as guiding the electron along its path.

Davisson and Germer investigated the scattering of a homogeneous pencil of electrons incident upon a crystal of nickel, and they found that under certain conditions sharply defined beams of electrons issue from the crystal and that these for the most part coincide in direction with the beams of Röntgen rays which would be emitted if these rays were incident at the same angle as the beam of electrons.

Transmission of Cathode Rays Through Solids. *Lenard Rays.*—It was for a long time believed that all solids were absolutely opaque to these rays, as Crookes and Goldstein had proved that very thin glass, and even a film of collodion, cast intensely black shadows. Hertz (*Wied. Ann.* 45, p. 28), however, showed that behind a piece of gold-leaf or aluminium foil an appreciable amount of phosphorescence occurred on the glass, and that the phosphorescence moved when a magnet was brought near. A most important advance was next made by Lenard (*Wied. Ann.* 51, p. 225), who got the cathode rays to pass from the inside of a discharge tube to the air outside. For this purpose he used

a tube like that shown in fig. 21. The cathode K is an aluminium disc 1·2 cm. in diameter fastened to a stiff wire, which is surrounded by a glass tube. The anode A is a brass strip partly surrounding the cathode. The end of the tube in front of the cathode is closed by a strong metal cap, fastened in with marine glue, in the middle of which a hole 1·7 mm. in diameter is bored, and covered with a piece of very thin aluminium foil about ·0026 mm. in thickness. The aluminium window is in metallic contact with the cap, and this and the anode are connected with the earth. The tube is then exhausted until the cathode rays strike against the window. Diffuse light spreads from the window into the air outside the tube, and can be traced in a dark room for a distance of several centimetres. From the window, too, proceed rays which, like the cathode rays, can produce phosphorescence, for certain bodies phosphoresce when placed in the neighbourhood of the window. This effect is conveniently observed by the platino-cryanide screens used to detect Röntgen radiation. The properties of the rays outside the tube resemble in all respects those of cathode rays; they are deflected by a magnet and by an electric field, they ionize the gas through which they pass and make it a conductor of electricity, and they affect a photographic plate and change the colour of the haloid salts of the alkali metals. McClelland (*Proc. Roy. Soc.*, 61, p. 227) showed that they carry a charge of negative electricity. As, however, it is convenient to distinguish between cathode rays outside and inside the tube, we shall call the former *Lenard* rays. In air at atmospheric pressure the Lenard rays spread out very diffusely. If the aluminium window, instead of opening into the air, opens into another tube which can be exhausted, it is found that the lower the pressure of the gas in this tube the farther the rays travel and the less diffuse they are. By filling the tube with different gases Lenard showed that the greater the density of the gas the greater is the absorption of these rays. Thus they travel farther in hydrogen than in any other gas at the same pressure. Lenard showed, too, that if he adjusted the pressure so that the density of the gas in this tube was the same—if, for example, the pressure when the tube was filled with oxygen was $\frac{1}{16}$ of the pressure when it was filled with hydrogen—the absorption was constant whatever the nature of the gas.

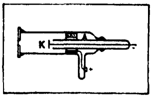

FIG. 21

Becker (*Ann. der Phys.* 17, p. 381) has shown that this law is only approximately true, the absorption by hydrogen being abnormally large, and by the inert monatomic gases, such as helium and argon, abnormally small. The distance to which the Lenard rays penetrate into this tube depends upon the pressure in the discharge tube; if the exhaustion in the latter is very high, so that there is a large potential difference between the cathode and the anode, and therefore a high velocity for the cathode rays, the Lenard rays will penetrate farther than when the pressure in the discharge tube is higher and the velocity of the cathode rays smaller. Lenard showed that the greater the penetrating power of his rays the smaller was their magnetic deflection, and therefore the greater their velocity; thus the greater the velocity of the cathode rays the greater is the velocity of the Lenard rays to which they give rise. For very slow cathode rays the absorption by different gases departs altogether from the density law, so much so that the absorption of these rays by hydrogen is greater than that by air (Lenard, *Ann. der Phys.* 12, p. 732). Ramsauer (*Ann. d. Phys.* 64, 513 [1921]; 66, 546 [1921]; 72, 345, 1923) discovered the very interesting fact that the absorption of cathode rays by the inert gases shows a remarkable diminution when the velocity of the rays is reduced below a certain value. Thus in argon the absorption when the velocity is that corresponding to a fall through one volt is only about $\frac{1}{10}$ of that when the velocity is due to ten volts, when the absorption is a maximum. The shape of the curves indicates that the absorption would be still less if the speed were yet further reduced. Thus the atoms of the inert gases seem almost transparent to very slow rays. Lenard (*Wied. Ann.*, 56, p. 255) studied the passage of his rays through solids as well as through gases, and arrived at the very interesting result that the absorption of a substance depends only upon its density, and not upon its chemical composition or physical state; in other words, the amount of absorption of the rays when they traverse a given distance depends only on the quantity of matter they cut through in the distance. The production of Lenard rays has been carried out on the grand scale by Coolidge in the laboratory of the General Electric Company, U.S.A. By the use of potential differences of half-a-million volts beams of rays several inches long at atmospheric pressure are produced and very interesting chemical effects observed.

Diffuse Reflection of Cathode Rays.—When cathode rays fall upon a surface, whether of an insulator or a conductor, cathode rays start from the surface in all directions. This phenomenon, which was discovered by Goldstein (*Wied. Ann.* 62, p. 134), has been investigated by Starke (*Wied. Ann.* 66, p. 49; *Ann. der Phys.* 111, p. 75), Austin and Starke (*Ann. der Phys.* 9, p. 271), Campbell-Swinton (*Proc. Roy. Soc.* 64, p. 377), Merritt (*Phys. Rev.* 7, p. 217) and Gehrcke (*Ann. der Phys.* 8, p. 81); it is often regarded as analogous to the diffuse reflection of light from such a surface as gypsum, and is spoken of as the diffuse reflection of the cathode rays. According to Merritt and Austin and Starke the deviation in a magnetic field of these reflected rays is the same as that of the incident rays. The experiments, however, were confined to rays reflected so that the angle of reflection was nearly equal to that of incidence. Gehrcke showed that among the reflected rays there were a large number which had a much smaller velocity than the incident ones. According to Campbell-Swinton the "diffuse" reflection is accompanied by a certain amount of "specular" reflection. Lenard, who used slower cathode rays than Austin and Starke, could not detect in the scattered rays any with velocities comparable with that of the incident rays; he obtained copious supplies of slow rays whose speed did not depend on the angle of incidence of the primary rays (*Ann. der Phys.* 15, p. 485). The discovery that cathode rays are accompanied by electronic waves throws a great deal of light on these effects. These waves as in Davisson and Germer's experiments cause some of the incident cathode rays to be scattered without loss of velocity in certain definite directions depending on the structure of the reflecting surface, one of their directions whatever be their structure will be that where the angle of reflection is equal to the angle of incidence. In addition to the scattering the incident beam produces secondary cathode rays of much smaller velocity. When the angle of incidence is very oblique the surface struck by the rays gets positively charged, showing that the secondary rays are more numerous than the primary.

Repulsion of Two Cathode Streams.—Goldstein discovered that if in a tube there are two cathodes connected together, the cathodic rays from one cathode are deflected when they pass near the other. Experiments bearing on this subject have been made by Crookes and Wiedemann and Ebert. The phenomena may be described by saying that the repulsion of the rays from a cathode A by a cathode B is only appreciable when the rays from A pass through the Crookes' dark space round B. This is what we should expect if we remember that the electric field in the dark space is far stronger than in the rest of the discharge, and that the gas in the other parts of the tube is rendered a conductor by the passage through it of the cathode rays, and therefore incapable of transmitting electrostatic repulsion.

Scattering of the Negative Electrodes.—In addition to the cathode rays, portions of metal start normally from the cathode and form a metallic deposit on the walls of the tube. The amount of this deposit varies very much with the metal. Crookes (*Proc. Roy. Soc.* 50, p. 88) found that the quantities of metal torn from electrodes of the same size, in equal times, by the same current, are in the order Pd, Au, Ag, Pb, Sn, Pt, Cu, Cd, Ni, In, Fe. . . . In air there is very little deposit from an Al cathode, but it is abundant in tubes filled with the monatomic gases, mercury vapour, argon or helium. The scattering increases as the density of the gas diminishes. No scattering takes place unless the potential fall at the cathode exceeds a certain value which is greater than the normal fall. The particles of metal are at low pressures deflected by a magnet, though not nearly to the same extent as

the cathode rays. The evidence as to whether the particles are charged or not is contradictory. From spectroscopic evidence V. Hippel (*Ann. der Phys.* 80, 672, 1926) concludes that the particles are uncharged *atoms* of the metal. Günter-Schultze (*Zt. f. Phys.* 38, 575) also comes to the same conclusion. According to Grandquist, the loss of weight of the cathode in a given time is proportional to the square of the current; it is therefore not, like the loss of the cathode in ordinary electrolysis, proportional to the quantity of current which passes through it.

Positive Rays or "Canal-strahlen."—Goldstein (*Berl. Sitzungsb.* 39, p. 691) found that with a perforated cathode certain rays occurred behind the cathode which were not appreciably deflected by a magnet; these he called *Canal-strahlen,* but we shall, for reasons which will appear later, call them "positive rays."

Their appearance is well shown in fig. 22, taken from a paper by Wehnelt (*Wied. Ann.* 67, p. 421) in which they are represented at B. Goldstein found that their colour depends on the gas in which they are formed, being gold-colour in air and nitrogen, rose-colour in hydrogen, yellowish rose in oxygen, and greenish grey in carbonic acid.

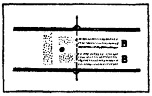

FIG. 22

The colour of the luminosity due to positive rays is not in general the same as that due to cathode rays; the difference is exceptionally well marked in helium, where the cathode ray luminosity is blue while that due to the positive rays is red. The luminosity produced when the rays strike against solids is also quite distinct. The cathode rays make the body emit a continuous spectrum, while the spectrum produced by the positive rays often shows bright lines. Thus lithium chloride under cathode rays gives out a steely blue light and the spectrum is continuous, while under the positive rays the salt gives out a brilliant red light and the spectrum shows the red lithium line. It is remarkable that the lines on the spectra of the alkali metals are much more easily produced when the positive rays fall on the oxide of the metal than when they fall on the metal itself. Thus when the positive rays fall on a pool of the liquid alloy of sodium and potassium the specks of oxide on the surface shine with a bright yellow light while the untarnished part of the surface is quite dark.

The method given previously for measuring the value of e/m for the cathode rays has been used by W. Wien and J. J. Thomson to determine the value of the same quantity for the positive rays. The theory of the method is as follows: AB and CD (fig. 23) are two equal horizontal plates connected to a battery of cells s that a constant potential difference maintained between this produces a vertical electric force X between the plates. M and N are the poles of an electromagnet, producing a vertical magnetic force H between the plates. A thin pencil of positive rays coming from a discharge tube containing gas at a low pressure passes horizontally between the metal plates and then strikes against a photographic plate, P. While passing between the metal plates the particles are deflected vertically by the electric force and transversely at right angles to the plane of the diagram by the magnetic forces. The vertical deflection x of the spot where the particle strikes the photographic plate by the electric field is given by the equation

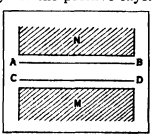

FIG. 23

$$x = \frac{Xe}{mv^2} l \left(L + \frac{l}{2}\right)$$

where l is the length of the metal plates and L the distance of the ends A and C of these from the photographic plate, v is the velocity of the particles the transverse deflection y due to the magnetic force H is, if the electric and magnetic fields are coterminous, given by

$$y = \frac{He}{mv} l \left(L + \frac{l}{2}\right).$$

If all the particles had the same velocity and the same value of e/m, the electric and magnetic forces would just deflect the spot from its position when these forces are absent to another position. If however the particles are not homogeneous as to velocity and the value of e/m the orginal spot will, under the electric and magnetic forces, be drawn out into a series of curves. Since

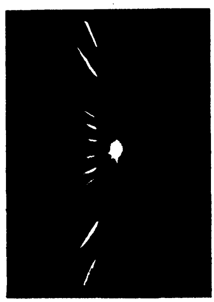
$$\frac{y^2}{x} = \frac{H^2}{X} \frac{e}{m} l \left(\frac{l}{2} + L\right)$$

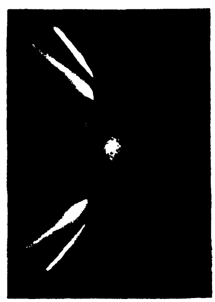
an expression which does not involve v but does involve e/m, if the particles were of the same kind but had different velocities, y^2/x would be constant so that the spot would be drawn out into a parabola, and by measuring the parameter of this we can determine e/m.

We see from the expressions for x and y that they cannot vanish unless mv^2 and mv are infinite. Since $mv^2/2 = Ve$ when V is the potential difference through which the particles have fallen, mv^2 cannot be greater than $2Ve$ where V is the potential difference between the electrodes of the discharge tube, hence x cannot be less than

$$\frac{Xl}{V}\left(L + \frac{l}{2}\right).$$

Thus the minimum value of x will not depend on e/m and will be the same whatever may the mass of the carrier of the positive charge. When there is only one value of e/m as in the cathode rays there will be only one parabola and the value of e/m deduced from the parabolas for these rays is $1{\cdot}78 \times 10$. With the positive rays the results are quite different, as will be seen from figs. 24 and 25, taken from J. J. Thomson's *Rays of Positive Electricity.* These are reproductions of the curves found on the photographic plate when the positive rays went through electric and magnetic fields—the horizontal deflection in due to the electric force, the vertical to the magnetic, for one-half of the exposure the magnetic force was in one direction for the other half in the opposite. It will be seen that instead of there being only one parabola there are many. The measurement of these shows that the greatest value of e/m is 10^4 which is the value of e/m for an atom of hydrogen; there is another parabola for which e/m is $\frac{1}{2} \times 10^4$ which is due to the molecule of hydrogen, another with $e/m = \frac{1}{12} \times 10^4$ due to the carbon atom, for the smallest parabola $e/m = \frac{1}{200} \times 10^4$. It is due to atoms of mercury vapour coming from the pump. This shows that the carriers of positive electricity are the atoms and molecules of the gases in the discharge tube;





BY COURTESY OF THE COUNCIL OF THE ROYAL SOCIETY

FIG. 24 FIG. 25

no carrier with a smaller mass than that of an atom of hydrogen has been discovered. It is to be noticed that atoms as well as molecules are always found among the carriers of positive electricity, and that when a compound gas is in the tube there is not only a parabola for the molecule of the compound, but one for each of the atoms of which the compound is composed, thus showing that the discharge is accompanied by a great amount of dissociation.

Some of the atoms occur with a double positive charge as well as with a single one, others may occur with one, two or three

charges, while the atom of mercury may have any number of charges from one to six. Many kinds of atoms show multiple charges, but these are very rare indeed on molecules.

In addition to the particles deflected in the direction corresponding to the positive charge there are some (*see* fig. 1) which are deflected in the opposite direction, and which are, therefore, charged negatively. These are particles which, after leaving the discharge tube and before arriving at the electric and magnetic fields, have lost their positive charge and acquired a negative one. It is remarkable that while every kind of atom can acquire a positive charge, the atoms of many elements seem incapable of doing so. The atoms of hydrogen, carbon, oxygen, chlorine are frequently found with negative charges, but a negative charge has never been found on atoms of nitrogen, helium, neon or argon. Again, it is very rarely that a molecule carries a negative charge, the only cases recorded are the molecules of oxygen and some hydro-carbons.

Retrograde Rays.—Thus, after the positive rays leave the discharge tube, some of them get a negative charge while others are found to be unchanged, so that the penal of positive rays has negative and uncharged particles mixed with it. An analogous effect occurs in the pencil of cathode rays streaming from the cathode. J. J. Thomson (*Proc. Camb. Phil. Soc.* ix., p. 243; *Phil. Mag.* xiv., p. 359, 1907), and Villard (*C.R.* 143, p. 673, 1906), have shown that the stream of cathode rays does not consist entirely of electrons; mixed with these are particles which are not nearly so much deflected by a magnet as the electrons; some are not deflected at all and are presumably uncharged; others are deflected in a direction indicating a negative charge; others in one indicating a positive one. These rays are called *retrograde rays*. J. J. Thomson measured the value of e/m for these rays and found that they consisted of positively electrified atoms and molecules of hydrogen, and atoms of oxygen and negatively electrified atoms of hydrogen and oxygen.

Use of Positive Rays for Chemical Analysis and for the Determination of Atomic Weights.—Positive rays supply a very powerful method of chemical analysis, for each kind of atom or molecule in the discharge tube produces a separate parabola and the measurement of these parabolas gives the value of e/m, and therefore of m. Thus the study of the photographs gives the atomic weight of the gases in the discharge. We can analyse a gas by putting a small quantity of it in a discharge tube and taking a photograph of the positive rays. This method of analysis has great advantages, for substances which can be obtained in the gaseous state it only requires a very small quantity of the substance and if a new gas is in the tube it is indicated by a new parabola; the presence of this not only shows that a new gas is present, it enables us to determine its atomic weight. By this means J. J. Thomson discovered the existence of H_3 and an isotope of neon.

Very great improvement in the accuracy of the determination of atomic weight has been made by modifications of the method made by Aston; he has made it by far the most accurate method of measuring atomic weights. He has obtained results of fundamental importance with regard to the relation between the atomic weight of the different elements, and has detected and measured the atomic weights of the isotopes of a large number of elements; an account of this work is given in the article ISOTOPES.

The positive rays show, when the pressure is not very low, the line spectrum of the gas through which they pass. An exceedingly valuable set of observations on this point have been made by Stark and his pupils (*Physik. Zeit.* 6, p. 892; *Ann. der Phys.* 21, pp. 40, 457). Stark has shown that in many gases, notably hydrogen, the spectrum shows the Doppler effect, and he has been able to calculate in this way the velocity of the positive rays.

Anode Rays.—Gehrcke and Reichenhein (*Ann. der Phys.* 25, p. 861) have found that when the anode consists of a mixture of sodium and lithium chloride raised to a high temperature either by the discharge itself or by an independent heating circuit, very conspicuous rays come from the anode when the pressure of the gas in the discharge tube is very low, and a large coil is used to produce the discharge. The determination of e/m for these rays showed that they are positively charged atoms of sodium or lithium, moving with very considerable velocity; in some of Gehrcke's experiments the maximum velocity was as great as $1{\cdot}8\times10^7$ cm./sec. though the average was about 10^7 cm./sec. These velocities are less than those of the positive rays whose maximum velocity is about 2×10^8 cm./sec. (J. J. TH.)

ELECTRICITY COMMISSIONERS. The Electricity Commissioners (Great Britain) were established in 1920 under the provisions of the Electricity Supply Act, 1919, for the purpose of promoting, regulating and supervising the supply of electricity in the United Kingdom (limited to Great Britain in 1922 on the transfer of Irish services). The objects of the Act, which was largely based on the findings of the Electric Power Supply Committee of the Board of Trade, were to secure improvement in the organization for the supply of electricity and to consolidate the administration of the then existing acts and orders relating to such supply.

The Act provided for the setting up of Electricity Commissioners not exceeding five in number responsible to the minister of Transport, with powers and duties which are indicated later; and for the transfer to the minister of the functions of the Board of Trade under prior acts, orders, etc., relating to electricity supply. It enabled the minister to exercise any of such functions through the commissioners, and provided that the minister should refer to the commissioners for their advice all matters connected with the exercise of the functions transferred to him, subject to certain exceptions.

The annual expenses of the commissioners, in accordance with an estimate prepared by them and approved by the minister, are defrayed by a levy upon the authorized electricity undertakings in the country, the expenses being apportioned on the basis of the number of units sold by each undertaking.

The principal functions of the commissioners are: (*a*) The preparation of technical schemes for the concentration of generation and the provision of main transmission systems, to be carried out by the Central Electricity Board constituted by the Act of 1926; and where necessary, the formation of electricity districts for the reorganization of supply therein under joint electricity authorities; (*b*) The sanctioning of the borrowing of money for such schemes by the Central Electricity Board, joint electricity authorities and municipal supply authorities; (*c*) The giving or withholding of consent to the erection of any new or the extension of any existing generating station other than a private station; (*d*) The granting of orders to authorize the supply of electricity in specific areas, the compulsory acquisition of land, etc.; (*e*) The framing of Regulations relating to the supply of electricity; (*f*) The prescribing of annual statements of account for all supply authorities, the collection of statistics, etc.

The commissioners advise the minister of Transport in the exercise of his powers connected, *inter alia,* with the granting of consents to the erection of overhead lines; the revising of maximum prices for electricity; the revocation of electricity powers in case of default, etc.; and reports to parliament on the provisions of private bills relating to the supply of electricity.

ELECTRICITY SUPPLY: COMMERCIAL ASPECTS. The conditions influencing the supply of electricity in Great Britain have undergone a number of important changes since the legislative foundation of the industry in 1882. The position now, nearly half a century later, considered in the light of subsequent legislation, presents some interesting phases of rhythmic evolution. The events may be grouped in three periods. The first was one of varying activities instrumented by trial and error—technically, commercially, politically. The second was one of fatigue and recuperation followed by splendid performance during the World War. The third is one of re-organization by the Electricity Commissioners. As a consequence, we reach the emergent conclusions that electricity can be transmitted more easily than coal, it can be sub-divided and applied more effectively than steam, and is more controllable than other forms of motive power. The industry offers scope for enterprise, for investment of capital, for employment of labour, which cannot be estimated

without appearance of exaggeration.

First Period.—The first of the three periods referred to covers about 25 years and deals with restrictive legislative conditions amid technical and financial difficulties which characterized the early struggles for survival of a young industry competing against firmly established gas interests, and later maintaining a defensive attitude against foreign competition developed under far-seeing encouragement. Public opinion in Great Britain in the latter part of the 19th century was adverse to the creation of further monopolies, the general belief being that railway, water and gas companies had received valuable concessions on terms which did not safeguard the interests of the community sufficiently. At the same time municipal institutions were given wider functions. These legislative measures were not uniformly successful; some proved injurious to the public, others discouraging to investors. One of these measures was the Tramways act (1870), which twelve years later was followed with the same political outlook by the first Electric Lighting act, imposing onerous conditions of expropriation. Stagnation during many years was the consequence, and recovery was slow. The aggregate capacity of the electrical plants installed in the United Kingdom in 1906 (24 years after the passing of the first Electric Lighting act) was only one million kw. The average load factor of all the British electricity stations was 14·5%. The average capital expenditure was about £80 per kw. of plant. The units sold were 530 millions. The average cost of generation and distribution, excluding depreciation and interest, was 2s. 3d. per unit.

With advances in technical practice the advantages of generation on a large scale, of distribution over wide areas at high voltages, and of application of electricity in various industries, were demonstrated in other countries, but in Great Britain special Acts of Parliament had to be promoted to authorize effect to be given to these principles. Before this could be done education of public opinion was necessary because strong opposition arose on the part of local authorities, who feared that municipally-owned electrical undertakings would be prejudiced. A joint committee of both houses of Parliament was appointed in 1898, with Lord Cross as Chairman, to consider the bills promoted by enterprising pioneers. This committee recommended that powers should be given for the supply of electrical energy over areas including the districts of several local authorities, and suggested that the then legislative conditions did not apply to such undertakings. While the Electric Power acts passed in 1900 were more consistent with economical development than the provisional orders granted under the acts of 1882 and 1888, the exclusion of the large towns from the acts, coupled with other restrictive provisions, disabled most of the Power act companies from raising the requisite capital, and progress under these special acts was at first very slow and difficult, because the sound policy of supplying cheap electricity in bulk had to be deferred. Successive bills were drafted by the Board of Trade to remove the obstacles, and eventually the Electric Lighting act (1909) was passed. It conferred wider facilities upon undertakers in minor matters, but the traditional attitude of restraining private enterprise in deference to views in favour of municipal trading permeated the measure, and afforded very little assistance towards building up a comprehensive system of supply. The conspicuous feature in this phase of electrical history is the hundreds of comparatively small generating stations, scattered and isolated throughout the country, supplying in restricted areas, and pursuing the uneconomic policy of independent development.

Second Period.—The second period (1909–19) presented during the first part the effects of disappointment due to unavailing struggles in the face of flourishing industrial conditions abroad. During this period Dr. S. Z. de Ferranti was president of the Institution of Electrical Engineers for two successive years. In his presidential address, Nov. 1910 (*Journal Inst. E.E.*, vol. 46) he expounded the "all-electric idea" of making an abundant and cheap supply of electricity available by a supply of electricity distributed over the country, with a view to coal conservation, production of home-grown food, and the better utilization of labour. This address is a sign-post indicating the main road of electrical progress which the present generation is treading, which in all probability will be followed not only by electrical engineers as pioneers, but by the whole army of British industrialists during the present century. In other addresses he made audible the demand within the industry for a "broader policy" in favour of better organized and more effective solidarity of the technical, commercial and political interests. The remarkable improvements which followed the adoption of this policy are best seen by a comparison of the contents of the *Journal Inst. E.E.* before and after the year 1913 (vol. 52).

The transition from a state of depression in the industry was hastened by the outbreak of the World War, followed by unprecedented demands for electric power in connection with production of war material. The war changed entirely the general aspects of the industry and initiated radical modifications in the legislative standpoint. The exigencies of the war revealed electricity as a vital agent of industrial production; they brought out sharply the defects in the legislative situation, by which co-operation in production and distribution was impracticable, and isolated development was fostered. The interconnection of generating stations, desirable with a view to economy in plant, coal and other items of cost, was urged upon electricity undertakers by a Board of Trade circular in May, 1916, and a special department was formed under the Ministry of Munitions to organize the supply of electric power. Despite chaotic conditions the great efforts made by the industry to cope with the urgent and practically unlimited call for power were generally successful. The four years of war were equivalent in electrical growth to that of the previous 35 years. The proof afforded of the great national importance of electricity supply led the educated public to think electrically. The following committees were appointed: coal conservation sub-committee of the reconstruction committee (Cd. 8880, 1917); electrical trades committee (Board of Trade Cd. 9072, 1918); electric power supply committee (Board of Trade Cd. 9062, 1918); committee of chairmen of the advisory council of the Ministry of Reconstruction (Cd. 93, 1919). These reports led to the passing of the Electricity Supply act, 1919 (amended by the Act of 1922). As originally drafted the bill met with much opposition, directed chiefly against its compulsory nature and what was regarded in many quarters as a distinct bias towards nationalization in its financial provisions. The contentious clauses were withdrawn, and provision was made for the creation of joint electricity authorities empowered to acquire generating stations and main transmission lines by agreement, but not otherwise. The act provided for the appointment of five electricity commissioners. Their general duties are defined as "promoting, regulating and supervising the supply of electricity." Their first specific duty was to determine provisionally "electricity districts," and consider schemes for improving the existing organization for the supply of electricity. Such schemes might provide for the establishment of joint electricity authorities representative of authorized undertakers, within the electricity district, either with or without the addition of representatives of county councils, local authorities, large consumers of electricity, and other interests within the district, and for the exercise by those authorities of the powers of the authorized undertakers. The machinery of the act was of a voluntary nature. The act as passed inspired confidence in the future of the industry; it broke down many prejudices, municipal, political and official; it simplified the procedure for extensions of supply areas, and in the general view constituted the one statesmanlike piece of legislation bestowed on the electrical industry. The appointment of electricity commissioners was in itself a salutary revolution. Their annual reports, the first to March 31, 1921, the seventh to March 31, 1927, are full and interesting records of important events and of beneficial work done.

Third Period.—The third stage covers the period from 1919 to the present time (1928). The year 1920 was not favourable to the task of embarking upon extensive schemes of industrial reorganization. The commissioners recognized the fact that "even if the problem could be reduced to engineering considerations alone, the financial stress would constitute a barrier to the speedy

development of schemes in different parts of the country." Not only was capital dear and rates of wages high, but prices of plant, materials and fuel were rising. The industry was faced also with the urgent problem of plant replacement. It was the policy of the commissioners not to consent to the establishment of new stations or the installation of additional plant, unless the proposals were technically and financially sound. But the needs were so urgent that often the commissioners found no alternative but to consent to the extension of uneconomical stations, in order that demands upon the undertaking might be met without failure of supply. The knowledge gained by manufacturers during the war had been so well assimilated that even during the time of acute trade depression, which succeeded the period of inflation, and notwithstanding labour troubles—which included prolonged disputes in the coalfields, culminating in the general strike (May 1926)—replacement and extension proceeded continuously. An appreciable portion of the work put in hand was expedited expressly for the purpose of stimulating the revival of trade and relieving unemployment, and in a number of such cases financial assistance was given by the Government to company undertakings by way of loans guaranteed by H.M. Treasury under the Trade Facilities acts. With similar objects in view advances were made (mainly to local authority undertakers) by the unemployment grants committee. As a further encouragement the Local Authorities (Financial Provisions) act was passed in 1921 to enable local authorities to suspend sinking fund payments on moneys borrowed for the construction or extension of revenue-producing works, while such works remained unremunerative, subject to a maximum period of 5 years.

In 1920–26 upwards of 100 (64 non-statutory) new generating stations were sanctioned, including four hydro-electric schemes in Scotland authorized by special acts. The largest of the new stations was of 100,000 kw. capacity, while 79 others were of smaller capacity than 250 kw. each. The figures of the smaller stations are of interest, inasmuch as they represent the inauguration of supplies in about 80 new localities, to which no alternative source of supply was available. This increase of generating facilities has been accompanied by a certain amount of concentration in large stations. The aggregate capacity of generating plant of authorized undertakers in 1927 was practically twice the capacity installed in 1920, but the actual number of stations in operation shows only a small decrease. The process of modernization has been marked by a notable improvement in the efficiency of generating machinery, due to advances in design and manufacture; by an increase in the size of units; and by change-over from direct current to alternating current.

Modern units ranging from 10,000kw. to over 30,000kw. now constitute a considerable proportion of the generating plant in operation, and nearly 90% consists of steam turbo-alternators. The combination of change of type and enlargement of units, coupled with improvements in steam-raising plant and advances in furnace practice, has effected important economies in the utilization of fuel. The lowest fuel consumption recorded at any steam station in 1926 was 1·36 lb. per unit, and the highest thermal efficiency 21·51%. Both figures relate to the Barton station of the Manchester corporation. The average consumption of fuel, coal, coke and oil, at steam stations was 2·43 lb. per unit, to which figure it has progressively declined from the 3·42 lb. per unit recorded in 1920.

The Growth of Supplies.—A conspicuous feature of post-war development has been the large extension of distribution areas, as many as 329 special orders having been granted during the period under review. The corresponding result in a view of the period as a whole, is seen in a progressive and substantial increase in the consumption of electricity. The sales of electricity by authorized undertakers in 1926 (excluding sales by non-statutory undertakings and the output of traction and private industrial plants) amounted to 5,723 million units. A hindrance to fuller development of the load is experienced in some areas by the practice in the past (which in some instances still prevails) of laying mains of a size too small to carry the increased demands now made upon them. The commissioners issued a memorandum on the subject in May, 1927.

For the purpose of ascertaining what steps were being taken to encourage and extend the use of electricity for domestic purposes; the relative effectiveness of such steps; and what further steps could be taken to bring about increased consumption, an advisory committee was appointed by the electricity commissioners in April, 1925. The committee's Report was published in Oct. 1926. It refers to the increasing use of electricity for domestic purposes, emphasizing the great potential demand and the value of the load to the supply undertaking, on account of its high "diversity factor," and includes an interesting and useful analysis of various multi-part tariffs at present in use. The committee formed the opinion that none of the latter could be recommended as standard for exclusive adoption.

Statistical Summary, 1926.—The industrial position of electricity supply in 1926 may now be statistically recorded. There were, in Great Britain, 623 separate undertakers holding statutory powers and owning between them 479 generating stations (264 local authorities and 215 companies) with an installed plant capacity aggregating 4,422,000 kw. (practically twice the capacity installed in 1920). The units sold to consumers were 5,724 millions, representing about 130 units per head of population. These figures relate to authorized undertakers only, but, including non-statutory undertakings, there are altogether 816 electricity supply undertakings with an aggregate capital of 283 million pounds (141 millions in respect of local authorities and 142 millions in respect of companies). The average return on the capital invested in the companies (debenture and shares) fluctuated between 5·58% in 1920 and 6·51% in 1925. For 1926, which was an abnormal year owing to the coal strike, the return fell to 6·21%. These figures reveal substantial expansion; nevertheless the progress made since the act of 1919, though considerable, was small compared with the potentialities of the industry and with progress in other countries.

The "Weir" Report.—The electricity commissioners in their annual reports made several references to the engineering, financial, administrative and legal obstacles to progress, and in their fourth report (Aug. 1924) they stated that though the powers vested in the commissioners had enabled progress to be made in securing co-ordinated development, it had become apparent that a real organization which would adequately serve the requirements of the country could only be achieved on the voluntary basis of the act of 1919, by a radical change in the attitude of authorized undertakers in general, and that, failing the early disappearance of the obstacles, the whole position would call for review. All parties in the legislature showed alacrity to deal with the problem, and in Jan. 1925 the Government appointed a committee consisting of Lord Weir of Eastwood (Chairman), Lord Forres and Sir E. Hardman Lever, Bart., with Sir John Snell as technical adviser, to consider the general question of the immediate and future electrical development of the country. The committee's report was presented to the minister of transport in May 1925, but was not published until March 1926, when a Government bill, based largely on the findings of the committee, was introduced in the House of Commons. The report recommended the establishment of a comprehensive network of transmission mains (called the "Gridiron") interconnecting all selected stations (43 existing ones and 15 new ones proposed) where generation would be concentrated, entailing the closing down of local generation at 432 existing stations. It further recommended the creation of a new body, termed the Central Electricity Board, with powers to construct, own and operate the proposed "Grid" system of high tension transmission lines; that selected stations should be operated by the owners under the directions of the board; and that all high tension energy generated by authorized undertakers in the country after a certain date should be generated under control in accordance with a technical scheme for the country, and sold through the board to all authorized undertakers at cost price. It proposed "not a change of ownership, but the partial subordination of vested interests in generation to that of a new authority for the benefit of all, and this only under proper safeguards and in a manner which will preserve the value of the incentive of private

enterprise." The report contains a picture of what should be aimed at to secure efficient generation of high tension energy in 1940 compared with the year 1925. The salient comparisons are given in the following table:

	Position (1925)	Position in 1940 or when the consumption has reached 500 units per head
Units sold per head of population	110	500
Maximum load	1,844,000 kw.	8,135,000 kw.
Kw. installed	3,096,000 kw.	10,000,000 kw.
Spare plant	68%	25%
Units sold	4,016,000,000	21,385,000,000
Load factor	24·9%	30%
Total capital:		
Generation	£73,680,000	£127,000,000
"Gridiron" transmission	..	£29,000,000
Distribution	£88,070,000	£243,500,000
Total revenue	£34,256,000	£88,100,000
Average price per unit	2·047d.	1d. or under

The Act of 1926.—The Government Bill framed to give effect to the recommendations of the "Weir" report was exposed to very keen criticism during its progress through Parliament. It is remarkable that whenever the industry is confronted by a serious crisis, it is not purely technical; not wholly industrial; not alone financial; but essentially political in its character. The opponents of the bill were not opposed to "super-power" developments. They agreed that standardization and systematic grouping, interconnection of existing power systems, generation on a large scale in efficient power stations, and transmission in bulk at high voltage to local distributors, would enable differential outputs to be adjusted, with beneficial results making for increased output, greater efficiency and economy; but they contended that these results could be better secured by other means and without the novel administrative system of control and economic methods proposed; and the owners of company electricity supply undertakings were nervous lest the proposed legislation should again inflict grievous financial and confiscatory burdens upon them. With considerable amendments of details the measure was finally passed and received the royal assent on Dec. 15, 1926 (16 and 17 Geo. 5. Ch. 51). By its enactment a radical change in legislative conditions affecting the organization of the electricity supply industry was brought about. A memorandum summarizing its provisions mainly from the standpoint of the powers, duties and obligations of authorized undertakers was issued by the electricity commissioners in Feb. 1927.

In order to secure the concentration of generation in a selected and limited number of stations, all interconnected and operated under one control, the act discards the principle of co-operative action on a voluntary basis (which was the principle embodied in the act of 1919) and substitutes a compulsory basis through the medium of a new body—the Central Electricity Board. This board, whose functions may be briefly described as the reorganization and control of generation, is established as an authorized undertaker for the whole of Great Britain, within the meaning of the Electricity (Supply) acts 1882–1922. The ultimate object in view is that all authorized undertakers shall obtain their supplies of electricity in bulk from the board, either directly or indirectly. For this purpose certain generating stations will be "selected" and interconnected, and operated by the owners on behalf and under the control of the board, who will purchase all the output of such stations at a price (being the cost of production) to be ascertained in accordance with prescribed rules. Distribution and commercial development is left in the hands of the undertakers as heretofore, who will purchase from the board the supplies they require (within specified limits) at a price, unless otherwise agreed, equal to the cost of production as ascertained and adjusted, plus a proper proportion of the board's expenses or according to the tariff fixed under the act, whichever is the lower. In the case of non-selected stations, the owners (being authorized undertakers) may demand a supply of electricity from the board, in which case they may be required to close down their local generating stations and take the whole of their supplies from the board. There are other circumstances in which the owners of a non-selected station may be required (by an order of the electricity commissioners) to close down local generation, namely when the Board notify that they are in a position to supply the full requirements of the undertaking at a cost below the then prevailing cost of generation at the station in question. The act does not contemplate the construction or operation, or the transfer of any generating stations to the board itself, except as a last resource, when they are unable to enter into an arrangement with any authorized undertakers or other company or person to operate such stations, or extend, alter or construct such stations as the case may be. The act contains various clauses for the protection of undertakers, but the commercial and, it is feared, the legal interpretations, are very involved. The board has power to borrow money with the consent of the commissioners and subject to regulations made by the minister of transport with the approval of the Treasury up to a maximum of £33,500,000, which money may be raised by the issue of central electricity stock, but power may be conferred on the board by special order to borrow in excess of that amount. The act makes provision for the preparation, adoption and carrying out of schemes of technical development ultimately covering the whole country. The Central Electricity Board consists of a chairman and seven other members appointed by the minister of transport "after consultation with representatives of local government, electricity, commerce, industry, transport, agriculture and labour." (Sir Andrew R. Duncan [chairman], Sir James Devonshire, K.B.E., Frank Hodges, Sir James Lithgow, Bart., W. Walker, Sir Duncan Watson, W. K. Whigham and Lt.-Col. the Hon. Vernon Willey, C.M.G.) The chief engineer and manager is Mr. Archibald Page (formerly an electricity commissioner). The secretary is Sir John R. Brooke, C.B.

Four schemes under the act have already been drawn up by the electricity commissioners and published by the Central Electricity Board. The first was transmitted by the commissioners to the central board and published by the board on May 11, 1927. It dealt with central Scotland, covering an area of about 4,980 sq.m. with a population of 3¾ millions, including roughly the whole of the industrial, shipbuilding and coalfield areas of Scotland. At the present time there are 42 authorized undertakers in the area, owning between them 36 generating stations. Under the scheme ten existing stations will be selected and operated for the board. The scheme contemplates the erection of two new stations of not less than 100,000 kw. each by the year 1938. The transmission system is designed in a series of ring mains, so that there will be alternative routes to points of supply. The primary line voltage adopted is 132,000 volts. The scheme involves a large measure of standardization of frequency—no fewer than eleven undertakings and five generating stations will have to be altered from 25 to 50 cycles. The scheme, with certain modifications, was adopted by the central board on July 1, 1927. The second scheme was transmitted on Sept. 29, 1927. It deals with south-east England, covers an area of 8,828 sq.m. including the London and home counties electricity district, and extends from Peterborough in the north to Brighton in the south, with a population of over 11 millions. The third scheme is for Central England and the fourth is known as the north-west England and north Wales scheme. Other schemes dealing with south-west England and south Wales are being prepared.

In the opinion of the commissioners the improvements in the organization for the supply of electricity which have taken place during the post-war period, will serve to facilitate the transition to the new régime laid down by the act of 1926. This important industry of nearly 50 years' standing is now for the first time placed under authorities able to deal authoritatively with technical, commercial and financial problems of the industry on their merits, in the national interests, in a large measure freed from local administrative restrictions. It is emerging from a state of bare existence to the full enjoyment of its life, with energies directed to rendering valuable services to the community. It has

an ill-advised inheritance of legislation, but a naturally strong constitution which enables it to regard difficulties and adversity as normal antecedents to technical success and commercial prosperity. As a matter of historical interest 12 years hence, it may be said that though the objections to many of the provisions of the 1926 act are valid, it is generally agreed that loyal and co-operative effort on the part of undertakers to make the operation of the act successful, is now more important to the realization of the all-electric idea than adverse criticism of the legislative machinery. The complementary condition of this consummation is all-round confidence that justice will be done in the difficult adjustments of rights, duties and interests between investors and workers on the one hand, and consumers on the other, having regard to past sacrifices and future services of the former and the paramount demand by the latter for cheap electricity as an essential to maintenance of national welfare.

The London Position.—After many years of controversy the problem of electricity supply in London is in process of solution. The limitations of the early electric lighting acts were sufficiently difficult in relation to provincial undertakings, but they were accentuated when applied to the metropolis. "London" is an agglomeration of towns and local authorities, and in the sense of the Electric Lighting acts the boundaries of a borough constituted the limits of an electric lighting area. Moreover, the generating station had to be erected within the municipal area of supply. The history of attempted reform of the London position dates back to 1905, and is summarized in *Garcke's Manual*, 1915–16, vol. xix., pp. 16–19, and 1926–27, vol. xxx., pp. 596–8 and 611–5. *See* also *4th, 5th, 6th and 7th Annual Reports of the Electricity Commissioners.* Nothing tangible was achieved until the London Electric Supply acts 1908 and 1910 were passed. Under these acts the powers to purchase the undertakings of the companies in the administrative county of London, which would otherwise have been exercisable for the most part in the year 1923 by the metropolitan borough councils, were modified, *inter alia* by extension of tenure to 1931, and transferred to the London County Council. Under the Electricity (Supply) act, 1919, the London and home counties joint electricity authority was established as from July 29, 1925. The district of the joint authority includes the whole of the counties of London and Middlesex, and parts of the counties of Herts., Essex, Kent, Surrey, Bucks. and Berks. The local government areas comprised in the district include the City of London, the City of Westminster, 27 metropolitan boroughs, 3 county boroughs, 16 municipal boroughs and a large number of urban and rural districts. The population at census of 1921 was 8,178,766; the assessable value on April 6, 1925, £75,926,030. The total number of authorized distributors is 89, namely, 44 local authorities and 45 companies. The position of the company undertakings was wholly altered by the London Electricity (No. 1) and (No. 2) acts, 1925, and the London and Home Counties Electricity district order, 1925. Under these the London companies secured an extension of the tenure of their undertakings until 1971, when such undertakings will be transferred to the London and home counties joint electricity authority. Prices to be charged for electricity and dividends to be paid to shareholders will be regulated by a sliding scale, and sinking funds will be set up by the operation of which the existing assets of the companies will be transferred to the joint electricity authority in 1971 free of cost, and new assets will be transferred at cost price less depreciation. Under the powers conferred by the London Electricity (No. 1) act, the promoters, namely, the City of London, county of London, south London, and south metropolitan companies, have prepared a scheme subject to approval by the electricity commissioners, under which the operation of the generating stations of the four companies would be directed by a joint committee. These generating stations have been joined by interconnecting cables. The remaining ten companies which promoted the No. 2 act have formed a new company now called the London Power Company, Limited, the board of which consists of a representative of each of the ten companies. This company has taken over the generating stations and main transmission lines of the ten companies, and these, retaining their full and complete rights as authorized distributors, now purchase in bulk from the London power company the whole of the electricity which they require for supply in the county of London.

Transmission and Distribution.—The present practice is to generate electricity at pressures of from 5,500 volts upwards to 66,000 volts, and to transmit the energy to sub-stations situated at convenient points of the low pressure distribution network where, in the case of alternating current supplies, it is transformed to the low distribution pressure for use by the consumers, and in some cases is converted to direct current of similar low pressure, ranging from 230 to 250 volts. The distribution network is provided with apparatus for isolating sections automatically or at will. From this low pressure distribution network the small service connections are made to individual premises for lighting, heating, cooking and other uses. In the case of factories and other industrial purposes the supply is provided at extra high pressure on the 3-phase system in the same manner as to the sub-stations, the consumer installing the transformers for reducing the voltage suitable to requirements. In the case of motors of a greater h.p. than 250, high pressure current up to 11,000 volts is often used without transformation. In the larger distribution areas the 3-phase system alternating 50-periods per second is now becoming standard. In thickly populated districts the standard practice is to employ cables with conductors insulated by paper impregnated with oil, surrounded by a lead sheath which, in many cases, is further externally protected by steel wire or tape binding, this system being employed for both high and low pressure cables. These cables are either laid direct in the ground or drawn into earthenware conduits at a depth of 2′ 6″ to 3′ 0″ below the surface. The alternative method of distributing electricity is to carry the conductors overhead.

The cost of providing cables underground is approximately three times that of overhead conductors of similar current-carrying capacity. In congested areas the density of the demand may justify the increased cost of underground cables, but the problem of distributing electricity in rural districts is now receiving attention; and to enable these services to be given at prices which the consumers can pay, the cost of distribution must be kept down, because the distribution network in rural areas is large in relation to number of consumers. Overhead lines outside the more congested centres of population are being increasingly adopted, but not sufficiently, if the rural load is to develop to the large extent which the potential demand indicates. The subject is closely bound up with questions of way-leaves and pole rentals, and the standard of construction demanded under the commissioners' 1923 code of regulations. A revised code of Overhead Line Regulations was issued by the Commissioners in April 1928 (El. C. 53). The high cost of construction imposes a handicap on development, particularly with low voltage lines. A memorandum on electrical development in rural areas was issued by the electricity commissioners in Aug. 1927, inviting the active support of local authorities, landowners and others able to afford facilities in connection with overhead lines and way-leaves. Further steps were taken in Nov. 1927 by a conference of various bodies interested in different aspects of rural electrification, to review the whole position. A report was issued by the Electricity Commissioners in July 1928. The Overhead Lines Association was formed in Oct. 1927 at the suggestion of Mr. R. Borlase Matthews, M.I.E.E., to co-ordinate experience and special knowledge of the subject.

Rural electrification points to ruralization of industries, with electricity distributed economically to factories on relatively cheap land. Decentralization of large composite works and segregation of factories for production of standard parts are easily conceivable developments. The social effects are not at present calculable, as many factors are still indeterminate, but the beneficial influence of these impending changes upon the relations between labour and capital, and upon the problems of unemployment, cannot be overlooked. The important point to note is that there is no national monopoly in electricity; it is an all-world development, with economic potentialities difficult to measure, with social and ethical probabilities interesting to contemplate. A few words on the subject of electricity in agriculture are apposite. Electro-farming is

an important recent development. As farms employ more power, in the aggregate, than all other industries put together, the capture of the farming load is most interesting from the point of view of the electrical engineer, and the fact that probably over a million of the world's farmers are using electricity (including 750 in this country) points to further advances. This new service has its own journals in Britain, America and Sweden, and a recently collected bibliography reveals the fact that over 600 authoritative articles, pamphlets and books have been written upon it, over 20% of which deal with electro-culture. In Great Britain, the most advanced electro-farming areas are Fifeshire, Ayrshire, south Wales, north Wales, Shropshire, Somerset and Cheshire, while near East Grinstead is an all-electric farm of 650 acres, where some 67 of the 200 known applications of electricity to agriculture are installed. In cities the annual consumption of electricity is based on units (kilowatt-hours) per square mile, but in rural areas it should be based on units (kw.hr.) per mile of distributor. On this basis, rural electrification compares very favourably with statistics available for suburban areas.

Manufacture.—The electrical manufacturing industry has experienced exceptional difficulties and undergone many vicissitudes. In its early days the various departments which are now developed as separate industries were closely allied. Thus the manufacturer was linked by various bonds, especially that of finance, with the inventor and *entrepreneur*, the parliamentary promoter of public utility undertakings, and the constructor of works, for he could not obtain employment for his factory unless he was interested in the initiation of enterprises. But during the World War the manufacturers gained experience in mass-production, and diverse industrial functions were segregated and became specialized. Subsequently in the post-war period of transient inflation, kindred businesses were again united by allied finance rather than in coalescence, and large combines of separate but interconnected companies were created for the furtherance of common interests and execution of large composite contracts. During the pre-war period when the industry was involuntarily inert, owing to impeded growth, manufacturers in America and in Germany, who had the encouragement of growing demand for apparatus, devoted their resources to the development of efficient selling organizations at home and abroad; with the result that they were able to take advantage of the system of free imports to secure orders in Great Britain for plant and machinery. The British electrical industry has been reproached for being in a backward condition, but the wonder is that it has got so far forward. Under changed surroundings after the war the electrical manufacturing branch recovered rapidly as compared with other branches of the engineering industry. Since the 1907 census of production the electrical output has increased from 13 million pounds to an estimated output of 80 millions in 1927, an increase of 500%, which is considerable in relation to the figures for general engineering products for the same period. The conspicuous progress of the industry is not by any means merely a quantitative increase. As Mr. Dunlop, the director of the British Electrical and Allied Manufacturers Association has shown, side by side with the growth in volume has proceeded a progressive improvement in quality and efficiency, the result of intensive research work for which the manufacturer had no funds under pre-war conditions. In the case of generating machinery, for example, fuel consumption has been reduced within the last five years by nearly 30%. Recent figures of exports indicate an advance relatively to other nations. In 1913 Germany dominated the electrical export trade of the world. In 1927, however, Britain has moved into the first place among electrical exporting countries. "The displacement of trading strength," says Sir Hugo Hirst, "justifies the assumption that the technical and manufacturing efficiency of British firms now stands at a higher point than at any previous time. In quality as apart from mass production their superiority can scarcely be challenged." It can be assumed, he says, that of the total production of electrical apparatus at least four-fifths represent direct and indirect wages paid. This means that the industry gives employment to probably 600,000 workers, or 320,000 in addition to the 280,000 it employs directly. The electrical manufacturer therefore is fighting for more than his own industry, and there are few industries in this position, at least of the same importance. The fact that an improved margin of profit has been earned need not be regarded as an effect of co-operation to keep prices above an economic level. As a matter of fact, the moderate improvement in net profits of electrical manufacture during the post-war period has been accompanied by substantial reductions in selling prices of electrical goods in relation to altered money values, cost of living, wages and other economic factors which enter into determination of price levels. An international comparison of prices in relation to costs of production is, however, rendered excessively difficult by variable classifications of manufactured goods, and by lack of information as to debit and credit items making up the effective costs for purposes of foreign competition. The history of the British electrical industry demonstrates in an accentuated form the truism that unrestricted competition leads to inability of an industry to do justice to essential interests of producer, consumer and community. Unduly low prices mean reduction and perhaps even elimination of profit, and this deters capital required for improvements, extensions and research, and produces disturbing conditions owing to fear of wage reductions; while consumers and users suffer in quality of commodities supplied and services rendered.

The following are financial figures relating to manufacturing undertakings in the three typical periods of the electrical industry:

Year	*Number of companies*	*Capital*
1910	265	£41,693,000
1920	280	£63,908,000
1926	365	£89,291,000

The average rates of net profits earned by such of the companies and firms whose accounts are published are for the year 1910, 5·22%; for 1920, 9·98%; for 1926, 7·73%.

The aggregate subscribed capital and loans authorized in 1926 of 1633 British electrical undertakings of all kinds amount to over £818 millions.

These undertakings are classified as follows:—

	£
Telegraph Companies	50,165,000
Telephone, Companies	9,251,000
Telephone, Government and Municipal Expenditure	72,735,000
Electricity Supply, Companies	142,470,000
Electricity Supply Municipalities, Loans authorized	140,568,000
Electric Traction, Companies	181,866,000
Electric Traction Municipalities, Loans authorized	89,686,000
Manufacturing	89,291,000
Miscellaneous	42,720,000
	£818,752,000

Research Work.—Following the rapid expansion of the industry during the war, it became evident that co-operative research was necessary for continued technical and commercial progress. An electrical research committee was formed in 1917, and a few years later this committee was reconstituted as the British Electrical and Allied Industries Research Association (E.R.A.) under the scheme of the department of scientific and industrial research which was established in 1918, the Government placing at the disposal of the department one million sterling to enable it to encourage the industries of the country to undertake scientific research. It is estimated that the membership of the E.R.A. represents about 85% of the capital employed in manufacture in the industry. The work of the E.R.A. now covers a large part of the field of research in the industry. The results are embodied in technical reports issued to members of the association, and about one-third of the reports have been published for the general benefit of the industry, mostly through the *Journal of the Institution of Electrical Engineers.* There are many problems which show great promise but which have to be postponed for lack of adequate funds, notwithstanding that the solutions are urgently needed. It must be added that large sums are being spent on research by individual firms; and that brilliant achievements are recorded in the field of theoretical physics, which, however, lead to further technical investigations for their practical application. In 1925 the electricity commissioners addressed representative sections of the industry with the view of enlisting active support for the work of the association.

Standardization.—Recognition of the principle of standardization arises early in the organization of every industry, but until a considerable degree of prosperity and solidarity is attained, by which individual interests and jealousies are merged in collective interests, its growth is slow. The first edition of the *I.E.E. Wiring Rules* was issued as early as in 1882, but it required many years before rival manufacturers could agree on standardizing even such small things as switches, plugs and lamps. In 1901 the British Engineering Standards Association (then called the Engineering Standards Committee) appointed a sub-committee for standardization of electrical plant. In 1906 Colonel R. E. Crompton founded the International Electrotechnical Commission, and the British National Committee was appointed to co-operate in this work. One of the many objects was to discourage the use of varying specifications by individual engineers when one specification would serve the purpose. The B.E.S.A. has now 70 committees preparing electrical specifications. The I.E.C. by its various committees is itself directly engaged in important co-operative standardization, and committees considering questions of electrical standards (mostly for reference to the B.E.S.A.) exist within various sectional electrical associations, while practically every industrial and scientific body in the electrical industry lends its active support to the work. In 1919 a Government inter-departmental committee was set up to co-ordinate the electrical requirements of the Government departments, and this committee works in close co-operation with the B.E.S.A. In 1925 the membership of the B.E.S.A. was made available to all connected with the industry on payment of an annual fee. The B.E.S.A. has endeavoured to set up standards of quality in materials and apparatus. Those standards are not confined to technical requirements, but are of value also on the commercial side, as is seen in the I.E.E. Model Conditions of Contract. Conditions of employment have also been standardized to a certain extent in the electrical industry. Probably one of the most valuable pieces of work brought to completion is the *British Standard Glossary of Terms used in Electrical Engineering.* The increase in production and the rapid spread of distribution of electric power on a large scale have created many new problems of standardization, for the consideration of which reference may be made to articles by Mr. P. Good in the *I.E.E. Journal*, vol. 64, April 1926, vol. 65, Jan. 1927, vol. 66, Jan. 1928.

Growth of Associated Effort.—Compared with the almost entire absence of solidarity in the industry previous to the adoption in 1912 and 1913 of "the broader policy" by the I.E.E. and various other bodies representative of electrical interests, there is now a marked improvement in the general organization for the promotion and protection of collective interests, and for collaboration on matters calling for joint examination and action. There are no fewer than 50 different associations, institutions and societies representing or concerned with diverse electrical affairs. There is not space to mention all; a full list appears in the *Manual of Electrical Undertakings.*

WORLD ASPECTS

From the standpoint of production and distribution, the pre-war progress of electricity in old countries was not commensurate with the advance and potentialities of the science. A study of the causes shows that the main deterrent factors are to be found in the complexity of the industrial organism and the social conditions of the particular country and period. The industries in general were firmly established on a steam-using basis; plant efficiency was high, and fuel cheap. Central power stations were therefore dependent for the most part on the advent of new industries or on a combination of circumstances in old factories which justified the conversion of steam to electrically-driven equipment, and the concomitant sacrifice of capital in the discarded installation. The element necessary for the economical generation of electricity, namely, a large and diversified demand for power, was absent or available only in a small degree. The standard of wages, too, precluded a considerable section of the people from adopting electricity for domestic purposes in preference to gas, the mains for which were laid in all the streets, whereas electrical distribution mains were, by reason of their almost prohibitive cost in relation to inadequacy of demand for current, confined to the principal thoroughfares and the better-class residential districts. But a new orientation has arisen: the adaptation during the war period of so many factories to electrical operation, the greatly increased cost of fuel which has deflected the scale against private steam plants, and the higher standard of living and domestic needs, constitute conditions which will enable the science of electricity to exercise a determining influence upon the future industrial and social development of European countries.

In new countries the door to electrical development was open from the outset; the field for enterprise was ready for exploration. Industries were few and of small extent. Gas, where supplied, was dear. Oil and candles were the mainstay for illuminating purposes. Legislation, if any, was benevolent. In a comparatively short space of time, communities, even those remote from the arteries of communication, contrived to harness the local streams and to enjoy the benefits of electricity supply. In the case of America, the virile genius of the people quickly surmounted initial difficulties standing in the way of obvious benefits to be secured; by the end of the nineteenth century a few large central stations had displaced many small stations, and electric current for all purposes was available over wide areas. The primary need was capital for new steam and hydro-electric undertakings and extensions of existing stations. The funds at command nationally were relatively meagre. European money, mainly British, was available, but in amount too small to meet the needs. Nevertheless, the progress in the United States was considerable. Electricity supply had opened up a vista of cheaper manufacture of commodities imported from overseas. The industrial instinct of the nation was awakened. Heavy, if not prohibitive, import duties were imposed. And thus, step by step, the United States emerged from an agricultural country into an industrial state with vast potentialities for home and export trade. By fertile combination of natural resources, growing population, intellect unhampered by national tradition, and with freedom from anxiety for conservation of capital investments in obsolete plants—all these causes, conjoined with the rapid accretion of wealth, have enabled the United States to occupy a place far ahead of any other nation in the domain of electricity supply, inasmuch as its installed generating plant capacity of 22 million kw. equals that of all the European countries combined. Canada, inspired by the example of its prosperous neighbour, made strenuous efforts towards development through the agency of its beneficent water powers; and not unsuccessfully, for with a population of only 9 million it has already installed more than 2½ million kw. of generating plant, whose output is largely utilized by the pulp and paper, mining and other industries which have contributed so much to the country's welfare. Other constituent parts of the British Empire—Australia and New Zealand, South Africa, India, the Crown Colonies and Mandated Territories—are markedly active in the development of their civic and industrial life by means of electricity supply derived from water powers, coal, oil, and plantation refuse respectively to local conditions. The great republics of South America, stimulated by the influx of foreign capital, have schemes for electricity supply throughout their territories, and bid fair to become large producers of current and users of electrical plant. Japan continues steadily to westernize its industries, and has an installed generating plant capacity exceeding 2½ million kw., and an estimated annual expenditure on electrical goods equivalent to £21 millions.

France, despite its war wounds, is forging ahead with ambitious electrical schemes, including networks of transmission lines and super-power steam stations in the industrial districts in the north, and hydro-electrical developments in the south. It possesses an installed plant capacity of over 4½ million kw. Belgium, with revived industrial activity, uses about 1½ million kw. of generating plant. Germany before the war, under the guidance and influence of its Government and the sustained assistance of its financial institutions, held a prominent, if not pre-eminent, position in the hierarchy of producers of electrical plant, and is again striving to recover supremacy. It has an installed plant capacity of about 6 million kw. 80% of the output of its public generating

stations is utilized for industrial purposes, or the same percentage as in the case of France; while the corresponding figure for Britain and the United States is only 65%. Scandinavia has over 2½ million kw. of generating plant installed, and Switzerland 6,900 hydro-electric undertakings operating 1½ million kw. of plant. The engineers of these countries enjoy a high reputation, and water turbines and generators of Swiss and Swedish manufacture are found in many of the principal hydro-electric installations in North America. The industrial position attained by both these countries demonstrates the enormous value of electricity in overcoming the handicaps of mountainous terrain and absence of coal deposits. Switzerland has the distinction of producing 750 kw. hours of electricity per inhabitant per annum, or more than that of any other nation. Italy has nearly 2,400,000 kw. of steam and hydro-electric plant in service, of which about 90% is used for industrial purposes; while a government commission is engaged (1928) in elaborate investigations of the country's resources and markets for electricity supply. Russia has rehabilitated its generating stations and erected many new ones, but awaits capital resources for industrial expansion. Spain has large existing and projected installations in the Pyrenean zone. The Netherlands, Czecho-Slovakia, and other countries of Europe also furnish evidence of substantial electrical progress.

The conference on the world's power resources held at the British Empire Exhibition at Wembley, London (June–July, 1924), under the aegis of the British Electrical and Allied Manufacturers' Association, and the patronage of the British Government, was epochal in the annals of electricity supply and of international relations. The conference was attended by representatives—technical, commercial, financial and legal—of foreign governments and of many electricity supply undertakings throughout the world. Papers were read by experts of no less than 22 different nationalities, who contributed to the dissemination of information calculated to further the progress of electricity supply in all its ramifications throughout the civilized world. The *Transactions of the Conference* (5 volumes, Lund, Humphries and Company, Ltd., London) rank among the most valuable contributions of modern times to applied science.

The following figures, extracted from publications by the B.E.A.M.A., indicate approximately the magnitude of the electrical industry in the principal countries of the world:—

Total Production of Electrical Goods	£600 million
Internal Consumption of Electrical Goods	£528 million
Exports (less Imports) of Electrical Goods	£ 72 million
Capacity of Generating Plant installed	53 million kw.
Output of Electricity	141,000 millions of units (kw. hours).

(E. Gar.)

UNITED STATES

Electric central station service in the United States is available in every city of 5,000 population or more; in 97% of all communities between 1,000 and 5,000; in 50% of all communities between 250 and 1,000; and in 25% of all hamlets of less than 250 inhabitants.

The electric utility industry, by which is meant the production, transmission and distribution of electric current by companies formed for that purpose and serving the general public without discrimination, had its birth in 1882 when Thomas A. Edison established the first central station in the world in New York City. This little Pearl Street station started with a few score customers in an area of 12 city blocks, and had a total generating capacity of 1,200 horse power. Current was used only for lighting, in electric arcs and the recently invented carbon-filament incandescent lamps.

In 1927, less than half a century later, the electric utility industry in the United States had a total of 21,694,000 customers, reaching about 80,000,000 of the population, and an installed generating capacity of nearly 40,000,000 horse power.

There are in the United States 4,400 electric utility enterprises, including both those privately and municipally owned. These represent an investment of more than 9½ billions of dollars, and require about one billion of new capital a year for maintenance, expansion and development.

Following the demonstrated success of the Pearl Street station, electric utility plants were built in city after city and town after town in rapid succession. Water-power at this early period began to be used to drive dynamos to generate electricity, though the difficulties of transmitting current over long distances made only favourably located water-power sites available for this purpose. The first hydro-electric central station was established at Appleton, Wis., in 1882, closely followed by the harnessing of Niagara Falls for the production of current for sale to the public. As late as 1891 the art of transmission was so little known that it was considered impossible to transmit power from Niagara Falls to Buffalo, 16 m. away. Niagara Falls now produces more than one million continuous horse power, part of which is transmitted 200 miles.

Growth and Control of the Industry.—The history of the electric utility industry through the remaining years of the century is a story of tumultuous but steady growth. Central station plants were built in increasing numbers, and since there was at this time no governmental control, fierce competition existed. Rival companies for the same city or district fought each other, and rates were cut until one company absorbed the other or they mutually ruined themselves, while the public demand for electric service steadily grew. Out of this early chaos came, State by State, the recognition that electric service was essential to the public well-being; that electric utilities were "affected with a public interest"; and that, for the benefit of the public, as well as of the companies, competition must give way to a State-regulated monopoly. Various kinds of regulation were tried, and from these has evolved the typical public service commission now in operation in every State but Delaware. Members of public service commissions are usually appointed by the governor of the State for a period of years, and serve as representatives of the public in the supervision and regulation of all public utilities, not electric companies alone. Water supply, gas, electricity, street railway, bus, express, telephone and telegraph companies are generally listed among public utilities.

The economic theory underlying regulation of public utilities is one of reciprocal benefit; in return for an exclusive privilege to serve a given territory and make use of public property, such as streets, the State assumes the right to supervise and regulate utility rates and standards of service for the benefit of the public.

Public service commissions have as their main function the assurance to the public of safe and adequate service at fair and reasonable rates. To this end they are given broad powers over accounting, financing, rates and service. Since it is equally in the public interest that a utility be able to maintain, improve and enlarge its service as the demand increases, it is also a function of public service commissions to see that properly managed companies are permitted to charge rates which will provide a reasonable return upon capital invested in furnishing the service.

It is under this general form of State regulation of private enterprise that the electric utility industry of the United States has made its extraordinary record of growth during the present century, to a point where the country uses nearly as much electricity as all the rest of the world.

The total cost of Federal and State regulation of public utilities and railroads in the United States is estimated to be about $12,000,000 a year, whereas the electric utility industry alone pays taxes aggregating more than 150 million dollars.

During the early years of the electric service industry numerous municipally owned and operated central stations were built. In many cases these were established in smaller communities, into which private capital was fearing to venture. The number of municipal enterprises increased from 815 in 1902 to a peak of 2,581 in 1922. Of this number, 1,820 operated generating plants, and the remainder purchased current for distribution. Privately owned enterprises in this same period increased from 2,805 to 3,615. Between 1922 and 1927 the number of municipal establishments decreased by more than one-fifth, and between 1917 and 1927 it is estimated that approximately 900 municipal electric enterprises throughout the United States were abandoned or put under private operation. Municipal electric companies in 1927

supplied less than 5% of the customers of the industry. The nationwide trend toward the consolidation of electric generating plants into interconnected, or so-called "superpower," systems has been an outstanding factor in the elimination of the small isolated unit. This development has applied peculiarly to municipal plants, which in the United States has tended to serve a restricted area only.

The relative economic merits of municipal and private operation of electric service systems is discussed in the 1927 report of the committee on public ownership and operation of the National Association of Railroad and Utilities Commissioners.

Quoting a detailed study of electric utilities under private and public operation made by the chamber of commerce of the United States, the report says, "In every count the advantage is with the private concern. Excluding taxes, operating expenses in the public plants exceeded those of the private plants by 20%. In the manufacture of current the cost to the public plant was found to be 33% more per kilowatt-hour than to the privately owned plants. The distribution of current cost 20% more. Labour costs were 53% more, and costs of fuel 13% more. The labour efficiency of the public plant was 26% below that of the private concern, while the loss of current through leakage showed an advantage in favour of the private business of 31%. As a general thing, utilities owned and operated by the public furnish inferior service to that furnished by privately owned and operated utilities. United States conditions thus present a direct contrast to British statistics.

An outstanding feature in the growth of the electric service industry in the United States has been the development, largely since 1914, of interconnected, or "superpower," systems, whereby transmission lines covering vast areas, sometimes several States, form great power pools, fed by a number of generating stations, both steam and water-power. These may belong to different utility companies, and may be widely separated. Increased reliability of service and economies of operation result from interconnection, while the widespread network of transmission lines makes service available to many communities otherwise without it, or ill-served by small and isolated plants. Electric utilities in the United States have built more than 135,000 miles of transmission lines.

Through the consolidation of smaller enterprises by interconnection, and the abandonment of uneconomic isolated plants in many parts of the country, the number of individual electric systems decreased 33% between 1922 and 1928, whereas the number of communities served by them increased by 5,000 or about 37%. The ultimate destiny of the United States is to be covered with a network of interconnected transmission systems fed by strategically located generating plants and reaching every community.

Output.—In 1927 125 electric utility systems produced 100 million kilowatt-hours or more of current each, and, of these, 18 produced a billion kilowatt-hours or more each. One single system, at Niagara Falls, generated nearly 4½ billion kilowatt-hours during the year, the largest individual production in the world. These 125 systems supplied more than four-fifths of the nation's electric power generated by utilities, and with additional current purchased by them for distribution, supplied 97%.

Increasing size of generating units, *i.e.*, steam turbines and high-pressure boilers, has continued, and whereas in 1910 a 10,000 kilowatt unit was considered large, 150,000 kilowatt units are now in service, and one of 200,000 kilowatts was recently constructed. With the construction of larger and more efficient plants, the coal required to generate one kilowatt-hour had decreased from more than 3 lb. in 1919 to less than 2 lb. as a national average in 1928.

The present installed capacity of all the central stations of the United States is approximately 36,000,000 horse power, of which 24,000,000 horse power are in fuel-burning plants, and 11,720,000 horse power in water-power plants.

The conservation of coal resulting from increased thermal efficiency in electric utility plants, as compared with 1919, was in 1927 about 5% of all the coal used in the country. And if the electrical energy used to drive industrial motors in 1927 had been generated by small factory plants instead of being purchased from the water-power and high-efficiency steam plants of the utilities, it is estimated that 40,000,000 tons of coal more than were used would have been burned. The average efficiency of the country's steam generating stations in 1927 was 40% higher than in 1919, and while the production of electricity from fuel has increased 107% since 1919, the actual consumption of fuel increased but 19%. The U.S. Geological Survey states: "In 1927 the operators of the public utility power-plants performed the remarkable feat of generating 2½ billion *more* kilowatt-hours of electricity with the use of 150,000 tons *less* fuel than in the previous year."

In 1925 the United States generated 40% of all the electricity produced in the world, but in yearly *per caput* use of current ranked only fifth among the countries, according to figures presented at the Economic Conference, in Geneva, covering that year.

Norway, with a *per caput* consumption of 2,200 kilowatt-hours a year, led the world. Second came Canada, with 1,150 kilowatt-hours. Switzerland was in third place with 990 kilowatt-hours. Others countries, in the order of their *per caput* use, were Germany, France, Great Britain, Italy and Japan.

In production of electricity the United States had almost three times that of the next country, which was Germany, their totals being respectively 66 and 22 billion kilowatt-hours. Great Britain in 1925 produced 11 billion, and was followed by Canada, France, Italy, Japan, and Norway, in that order. The figures for the United States and Canada cover only electric utility plant output, while for the other countries all generating plants are included.

Of a total production by electric companies in the United States in 1927 of 75,116,000,000 kilowatt-hours, about two-thirds was produced by fuel burning plants, and one-third by water-power.

There is available for development in the United States water-power totaling approximately 50 million horse power, but it must be pointed out that a large part of the still undeveloped water-power is not economically feasible under existing conditions of construction costs and markets and the severe competition of modern steam generating plants.

California ranks first among the States in public utility water-power installations, with nearly two million horse power. New York, with 1,528,000 h.p., is second and the State of Washington, with 663,490 h.p., is third.

Use of Electricity.—The growth of interconnection and improvements in the art of electrical transmission and distribution is making electric service available to a steadily increasing number of villages and rural districts throughout the country. This flow of power is profoundly affecting American life, economically, socially and industrially.

For a number of years after the establishment of the first central station, electricity was used almost exclusively for lighting purposes. The earliest recorded use of an electric motor driven by central station power to do commercial work is about 1883, when a small motor is reported to have been set up in a grocery shop near the Pearl Street station and used to grind coffee. In 1927 electricity furnished 70%, or nearly three-fourths, of all the 41,000,000 h.p. used in American industry, and provided more than three horse power for every wage-earner. In 1900 there had been available only one-tenth of one h.p. per worker.

Between 1913 and 1928 the total electrical energy generated by the utilities of the country increased six times; the energy used for lighting increased six times, and that used for power increased eight times. Nearly 75% of the current produced is generated in the Atlantic and North Central States.

Despite the fact that the United States uses nearly as much electricity as the rest of the world, that country ranks only fifth in proportion of homes equipped for electric service. Switzerland is first, with 96.5% of her homes electrified. Japan, Denmark and Canada follow in that order, followed by the United States with 62% of her homes so equipped. Each of the countries leading the United States has large hydro-electric resources and relatively short transmission distances to contend with, and most

of their homes are in compact areas. There are more than 17½ million electrified homes in the United States, approximately as many as in the rest of the world, but tremendous areas of sparsely settled country have retarded the development of electric service therein. New York State has the largest number of electrified homes, with 2,550,000, or more than 91% of the total number. Illinois and Pennsylvania follow, with about 1,450,000 each, and California is third, with 1,336,000.

Twelve per cent of the electricity generated by American utility companies is used for domestic purposes. This branch of the service produces approximately 30% of the gross revenue of the electric utilities, but while the average domestic rate is 3.28 times the commercial rate, it is to be considered that the average commercial customer is a wholesale purchaser, using more than 30 times as much as the average home.

Following the development of the electric incandescent lamp and the widespread establishment of central stations in the United States, small motors were perfected and the use of electric household labour-saving appliances began. It is impossible to obtain exact figures on the numbers of such appliances in use, but the following estimates, for 1927, are below rather than above the actual totals:

Electric irons	13,500,000
Vacuum cleaners	11,000,000
Clothes washers	4,750,000
Electric fans	4,600,000
Toasters	4,500,000
Heaters	2,300,000
Electric ranges	600,000
Electric refrigerators	500,000
Ironing machines	350,000

These are the more widely used appliances for the home. A complete list would include dishwashers, radiators, sewing-machines, percolators, violet-ray outfits, heating pads, waffle-irons, hot plates, floor polishers, hair curlers, radio sets and many others.

High wages and increased purchasing power have made the American home the greatest user of electric appliances of any in the world. To the 17½ million homes equipped for electric service, additional homes are being added at a rate of about 1½ million yearly.

Rural Electrification.—The adoption by agriculture of electric power is a relatively recent development in the United States, and is playing a twofold part: first, by providing the farmer with a reliable, flexible source of power for farm work; and second, by providing the farm home with electric light and other mechanical comforts hitherto available only in towns.

The increasing interconnection of utility systems, with their far-reaching transmission lines, has been a notable factor in rural electrification, in addition to which thousands of miles of rural lines have been built in farming districts. It is estimated that in 1928 there were 400,000 farms taking electric service from utility companies in the United States, about 6% of the total number of farms. Between 1923 and 1926 the number of electrified farms increased by 86.6%, at which rate there will be one million such farms in the country at the end of 1932.

California, where electric power is widely used for irrigation, leads the other States, having 62,000 farms served by the companies. New York, with 44,000, is second, and the State of Washington, with 21,000, third.

Electricity in the farm home is used as in the urban dwelling, for light and to drive labour-saving appliances. Electric power for farm work is being economically used for a wide variety of purposes, among them: automatic water systems, baling presses, bone grinders, milk bottle washers, brooders, churns, cider mills, clippers and shearers, concrete mixers, corn shellers, cream separators, drills, fanning mills, feed grinders, hay hoists, incubators, limestone grinders, milking machines, potato graders, milk refrigerators, saws, shredders, silo fillers, sorghum mills, sprayers, threshers and others.

Rural electrification in the United States is being hastened by the combined efforts of the utility companies, national and State Governments, through farm experiment stations and agricultural colleges, and other organizations. This work falls into two general divisions: first, the application of electrical energy to present farming practices, and second, the development of new practices and farm equipment for which electricity may be peculiarly suited. Seventeen experimental rural lines have been built in as many States, and are serving as field laboratories. Information derived from their operation by utility companies, equipment manufacturers and agricultural experts is used both to avoid costly errors and to speed rural electrification to a sound and productive development.

Electricity in Industry.—It is probable that the application of electric power to industry in the United States has been the single most important contributing factor in the past quarter-century to the country's material prosperity. Increased individual production, greater efficiency, higher wages and higher standards of living have followed this phase of electrical development, and it is estimated that the American worker had in 1927 a real wage nearly double that of any in Europe.

Between 1914, when the demand for war material stimulated American industry of every sort, and 1925, the output of American factories, mills, and other plants increased by 70%. During the same period the power used increased by 61%, virtually the entire increase being electrical. In this time the number of workers increased only 21%, indicating the greatly augmented output per worker.

Significant changes in industrial operation appear in recent industrial electrification. Between 1919 and 1925 the use of primary power in the United States increased 22%, from 29,300,000 to 35,775,000 horse-power. There was in this period almost no increase in boilers and engines installed in plants. The increase of more than 6 million horse-power was practically all in electric motors driven by power furnished by electric utility companies.

It is estimated that there are installed in American industrial plants electric motors which in 1927 consumed more than 38 billion kilowatt-hours of energy, as compared to less than 20 billion kilowatt-hours in 1920. The cost of all power and fuel, the latter including fuel used to produce heat as well as power, is about 6½% of the "value added by manufacture," and about 2½% of the total value of the finished products.

Interconnection and the wide distribution of electric service has had a further effect upon American industry in liberating the manufacturing plant in its choice of location. The factory no longer has to go to a power source; power comes to it. With electric service to be had nearly everywhere, factories have been made free to consider other elements such as transportation facilities, markets, availability of raw materials and labour. Thus small towns are increasingly often chosen as factory sites because of the better living conditions for the workers. Decentralization of American industry is becoming an actuality. The use of electric motors and power purchased from the utility companies obviates investment in boilers and engines by factories, and so releases large sums of capital for other purposes, and facilitates the establishment of new factories.

The most recent authentic figures upon the electrification of industry are those for 1925, completed by the U.S. Census of Manufactures. These indicate the following percentage of electric power used, in relation to all power, in various industries: machinery manufacture 95·7; transportation equipment, including automobiles, 95·1; rubber products, 91·7; non-ferrous metals, 89·6; tobacco products, 87·1; leather products, 83·3; stone, clay, glass, etc., 80·4; textiles and their products, 74·6; food and kindred products, 65·7. The average for the 16 major industries examined was 70% of electrification, a proportion which has since then materially increased. These industries had installed motors aggregating more than 25 million horse-power, of which nearly 16 million horse-power were supplied by energy purchased from the electrical utilities, and the rest by generators in the plants.

Finance.—Electric service rates in the United States are based upon the value of property "used and useful" provided by the company to furnish the service. It is held that upon such a valuation the utility is entitled to earn a "fair and reasonable

return."

The increasing efficiency in generating and transmitting current, and the economies achieved in the operation of large, modern plants, and interconnected systems, have produced a virtually uninterrupted downward trend in electric rates in the United States, particularly in domestic rates. These, in 1928, averaged for the country as a whole 15% less than in 1913, and were the only item on the Government's cost-of-living list to show a decrease to a point below pre-war averages. In 1882 the price paid by household users was 20 cents a kilowatt-hour. In 1926 it was 7·4 cents. In 1913 "cost-of-living" dollars, based on figures of the Bureau of Labor Statistics, this latter price was equivalent to 4·2 cents a kilowatt-hour. Thus domestic rates have been reduced not only relatively, but absolutely. No other industry, it is believed, can show a similar record.

The electric service industry of the United States represented in 1927 an investment of $9,500,000,000. To maintain and expand the service, approximately $1,000,000,000 of new capital is required yearly. In 1926 American electric utilities sold securities of the value of $1,390,000,000, a total which was more than one-fourth of the country's entire security sales for that year. Of this sum, $370,000,000 were used for refunding purposes, and the remainder for improvements and extensions to meet increasing demands for service. (The sale of electric utility securities in 1926 was greater than those of the railroads, iron, steel, copper, coal, automobile, oil, rubber and shipping industries combined.)

In 1927 the electric service companies raised $2,100,000,000 and expended $760,000,000 for additional facilities. Their 1928 budget was more than $900,000,000. Savings-banks, insurance companies, universities, colleges and other organizations are among the heaviest purchasers of electric company securities. American savings-banks alone have invested more than 300 million dollars, and insurance companies nearly a billion dollars in this industry. Nineteen states have passed laws permitting savings-banks to purchase utility bonds.

A feature in the financing of electric service companies, and to a lesser degree other utilities, has been the development chiefly since 1914 of "customer-ownership," *i.e.*, the direct sale of their securities, chiefly stocks, by individual companies to the people using their service and to their employees. It is estimated that in 1926 there were nearly 1½ million customer-owners of the electric service industry, holding more than 13 million shares of stock. To these were added in 1927 the investment of $240,000,000, through 344,000 individual sales, an average of about $700. Nearly 1½ billion dollars' worth of electric utility stock has been sold to customers and employees since 1920. A single issue of stock sold on this plan showed purchasers in 57 trades or occupations, and included bakers, barbers, bricklayers, butchers, carpenters, domestics, dressmakers, janitors, mail carriers, mechanics, nurses, plasterers, plumbers, policemen, railroad men and seamen; also artists, bankers, dentists, doctors, lawyers and clergymen.

The capitalization of American electric utilities has increased from about 600 million dollars in 1900 to more than 9½ billions in 1928, about evenly divided between stocks and bonds. Upon this investment the industry in 1927 had a gross income of $1,783,000,000, indicating an investment of nearly five dollars for each dollar of gross income. The net income was $1,017,000,000. Of the total income, about $1,075,000,000 was paid by lighting customers; $517,000,000 by power customers; $60,000,000 by electric railways. Intersales between utility companies accounted for $129,000,000. This last item reflects the effects of interconnection and the flexibility of the power supply over large transmission systems. Sales of current between companies doubled from 1923 to 1928, and in amount constitute about one-fifth of all the energy generated. In spite of these very large inter-company sales, less than 10% of the current produced by American electric utilities is sent across State boundaries.

Electric service companies in the United States, with other utilities and the steam railroads, pay a higher percentage of their gross receipts in taxes than any other corporate group. (This does not include municipal or Government owned central stations, which are virtually tax-exempt.)

For each dollar of gross income, electric utilities pay more than nine cents in the form of Federal, State, county and local taxes. This is a tax rate which has risen steadily from 3½ cents in 1902. In 1927 the electric utilities contributed to Federal, State and local Governments taxes aggregating more than $150,000,000. Of this sum, approximately one-third was collected by the Federal Government and two-thirds by the State, county and municipal Governments. The ramification and variety of taxes appear in the following list of 11 taxes paid by one New York State company:

Name of tax	*Assessed by*
Gross earnings tax	State
Excess dividend tax	State
Real estate tax	Cities, towns, villages
Franchise tax	Cities, towns, villages
Auto and chauffeur license	Municipality
Street sprinkling, snow removal, etc.	City
Improvement taxes	City
Capital stock tax	Federal Gov't
Federal income tax	Federal Gov't
Excise taxes	State Gov't
Bond interest withheld	Federal Gov't

The growth and development of the electric utilities in the United States have been almost unparalleled in the history of industry. In capital invested it ranks fifth, the four larger industries being agriculture, the largest, railroads, automobile manufacturing, and construction, in the order named. In value of products, electric utilities industry ranks 13th, and in number of employees the same.

Peculiar Uses of Electricity.—Electrical energy, in the form of light and power, has been applied to thousands of different tasks. Many of them are familiar to nearly everyone, while others are known only to the specialists who are using them. A few of the curious and interesting things done by electricity are here listed.

A new electric signal system stops machinery at the cry of "Help." This is done by wireless waves and a microphone so selective that it reacts only to the key-words chosen.

An electric arc burning in neon gas has been developed which glows with a brilliant red light and has the power to pierce fog.

A single tank, heated by electricity, melts 45 tons of zinc at one time, for galvanizing.

Electric lights of specific colours are being used to attract insect pests of different sorts in orchards and gardens.

Rays from ultra-violet lamps are being used to sterilize the water in indoor swimming-pools.

An automatic electric welder welds 150 ft. of seam an hour on steel pressure tanks without guidance or assistance.

Fish are "shocked" away and saved from turbine wheels of hydro-electric plants by a pair of electrodes which set up an electric field in the water nearby.

Wheat has been grown to maturity, entirely by electric light, in 13 weeks, the grain being put in jars of water containing the necessary food elements.

An electric motor has been built no taller than a housefly, weighing a quarter of an ounce and consisting of 58 parts. It develops 400 revolutions a minute.

Violet rays from electric lamps are being used on cows and chickens to produce better milk and more fertile eggs.

Bullets in flight are photographed by means of an electric spark in a dark chamber.

Electricity weighs a moving web of paper as it is produced, through a tuned radio circuit. The paper passes between two metal plates and any variation in thickness affects the response of the circuit. The variation is recorded on a meter. (M. S. S.)

ELECTRICITY SUPPLY: TECHNICAL ASPECTS.

The supply of electricity may be either (1) a private supply on a small scale for electric lighting in an isolated country house, hotel, institution or ship, or else on a large scale by a railway company or local authority for purposes of lighting, traction, or power for their own use; or it may be (2) a public supply by a limited company, corporation, local authority or government for general supply of electric current to the public for light, heat, power or other purposes. In the latter case the commodity sold is

energy in the form of electric current supplied for a certain time at a specified voltage or pressure and reckoned and charged for at a certain price per kilowatt-hour or Board of Trade unit. (B.T.U.).

The invention of the carbon filament, electric incandescent lamp in 1880 and 1881 by T. A. Edison, J. W. Swan and C. H. Stearn made possible domestic electric lighting by private and public supply and this began to be undertaken in 1882. It necessitated the manufacture of constant voltage dynamos for supplying current to a number of lamps arranged in parallel between two conductors (*see* DYNAMO), and a number of small inventions such as sockets for lamps, switches, fuses and switch-boards. The conductors in buildings are nearly always high conductivity copper stranded or single wire which is tinned and insulated with vulcanized india-rubber and protective hemp. These are run in pairs in steel conduit tubing placed under floors or behind plaster of walls. In some cases twin insulated wire is enclosed in a continuous lead sheathing and used with or without steel conduit tubing.

The lamps now used have a filament of drawn tungsten wire. They may be vacuum lamps in which the bulb is highly exhausted or gas-filled lamps containing argon or some neutral gas. The vacuum lamp when properly incandescent gives light at the rate of 1¼ watts per candle power and the gas-filled lamps about ½ watt per candle power (c.p.). Hence a 16 c.p. vacuum lamp takes about 20 watts.

Private Installations.—In arranging an electric supply by a private plant the first step is to mark down on a plan of the building the position of every lamp required and to estimate the maximum number of lamps which may be in use at one time. From the wattage of each lamp the total electrical power required can then be determined and it is a safe rule to install dynamo and engine plant for double this maximum. The position and type of motive power, whether steam, gas, or oil engine, can then be determined. For such plants it is best to use a supply voltage of 100, unless the generating plant must be placed far from the installation. It is also usual to install a storage battery to give supply during the night and to preserve continuity of supply at all times. The dynamo must then be able to give the necessary maximum voltage required to charge the cells, viz., 2·6 volts per cell, and for 100-volt installation it is usual to employ 55 or 56 cells with a regulator for controlling the number of cells put in connection with the supply line. An automatic cut-out must be provided to prevent current coming back through the dynamo in case of failure of motive power.

If perfect security from interruption of supply is required then the engine and dynamo plant must be duplicated, each part being equal to maintaining the full supply. The engine-room must be equipped with current and volt-measuring instruments and cut-outs and switches so that the engineer in charge can know at all times the state of the plant and have control over it. In the building itself the main supply cable from the storage cells terminates at a main switch-board of slate or marble fitted with double-pole switches and fuses for each branch circuit. These branch circuits run without break or joint to distributing boxes on the various floors from which again sub-circuits are run to each room. These sub-circuits terminate in double-pole fuses on the distributing boards. No such circuit should carry more than 1 to 3 amp. of current. The whole wiring installation should be put in in accordance with the wiring regulations of the Institution of Electrical Engineers or of the principal fire insurance offices to secure safety from fire. The insulation of the whole installation should be tested on completion of the wiring contract.

The Institution of Electrical Engineers' (I.E.E.) rule for direct current installations is as follows. The insulation resistance with all lamps and fuses in place and switches on shall be measured by applying between earth and the whole system of conductors, or any section thereof, a direct current pressure of not less than twice the working pressure and the insulation shall not be less than a number of megohms equal to 25 divided by the number of lighting points on the system. Thus for a 100-lamp installation it must not be less than ¼ megohm.

It is usual also to test each side of the system with all lamps removed from sockets. The actual size of wires or conductors put in is chiefly determined by the permitted drop in voltage at the most distant point on the system between full load and no load. It is generally limited by specification to not more than 2 or 3% of the standard supply pressure. Thus for 100-volt supply the voltage at the point most remote from the entrance switch-board must not rise to more than 102 or 103 volts when all lamps installed are switched off compared with its voltage 100 when all lamps are on. The installation should be tested for insulation from time to time and any defect immediately remedied.

For private country-house installations there is a very extensive use of small direct current dynamos coupled direct to an internal combustion engine worked with petrol or paraffin, and these are so arranged that they may be operated without skilled labour. This generator is commonly associated with a suitable storage battery so that the plant can be run during the day and stopped at night. With care a good battery should last 15 years but the life of the positive plates can easily be very much abbreviated by careless use, overcharging or allowing to stand unused and partly discharged.

Various Systems of Supply.—For large private installations of electric supply plant for purposes of either lighting, power or traction there is a choice of several different types of electric current according to the requirements of the case. The supply may be in the form of: (1) direct or unidirectional current and utilized by lamps or direct current motors; (2) single-phase alternating current used on lamps or alternating current motors, or rectified by mercury arc rectifiers and used to drive direct current motors, or (3) the supply may be in the form of three-phase alternating current which may be used for power with induction motors or rectified for use with direct current motors. In the case of direct current plants of any magnitude it is economical to employ the three-wire system when the supply is for lighting chiefly or only small motors.

In this system (*see* fig. 1) as used also for public supply, there are three bars on the main switch-board called positive, middle and negative, O_1, O_2, O_3. From these proceed sets of three underground or overhead conductors called feeders, F_1, F_2, F_3, which run to the area of consumption. They connect into three other sets of conductors called distributing mains, D_1, D_2, D_3. The consuming devices H_1, H_2, either lamps or small motors, are connected in about equal number in parallel between the positive (+) and middle main (M) and the negative (—) and middle wire (M). Between the positive and negative bus bars are connected the direct-current generating dynamos giving a voltage equal to double that required for the lamps or consuming devices placed on the two sides of the middle wire. If the number of such lamps or total current taken by them all is equal on the two sides of the middle wire then this last will serve merely to distribute the current differently to lamps on the two sides of the middle wire. If, however, the current demand on the two sides

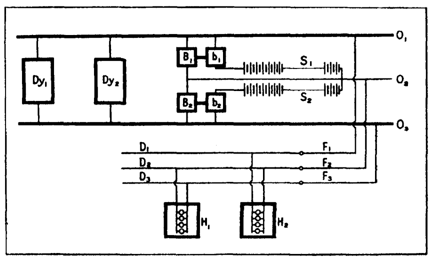


FIG. 1.—DIAGRAM OF THE THREE-WIRE SYSTEM OF ELECTRICITY SUPPLY

Dy_1, Dy_2 are separate steam dynamos connected with omnibus bars, O_1, O_2, O_3. F_1, F_2, F_3 are three parts of the switchboard; D_1, D_2, D_3, the positive, middle and negative distributing mains; B_1, B_2, balancing machines; b_1, b_2, small dynamos known as "boosters"; S_1, S_2, storage batteries, and H_1, H_2, houses supplied from the plant

is unequal, their two shunt-wound direct current generators B_1, B_2 with very low resistance armatures have to be joined across the outer mains in series and their junction point connected to the middle wire. These machines are called *balancers*. If then the outgoing current in the positive main I_1 is greater than the return current I_2 in the negative main, the difference I_1-I_2, called the out-of-balance current, returns along the middle wire. Half of it passes each way into the balancer armatures. The machine on the negative side becomes a motor and drives the other machine as a generator and the latter supplies the out-of-balance current.

The equality of voltage on the two sides is improved by connecting the fields of the balancers in series across the outer mains but so that the current enters the field of the negative side balancer first at that end nearest the negative main. If it is desirable to employ storage batteries to assist supply at heavy loads or for supply during the night then each battery on the two sides must have in series with it a direct current dynamo called a *booster* to add to the main generator voltage the extra volts of 0·6 volt per cell required to charge the batteries. These boosters have their shafts directly coupled to the balancers and are driven by them. The booster voltage is regulated by resistance inserted in their shunt-field circuits. The ideal condition desired is that the main generators should work under constant load so that when the external load of lamps or other devices is light, the battery would be charged, and at times of heavy external load the battery would discharge and supply the excess current required, the terminal voltage remaining all the time constant. This condition, however, is difficult to fulfil, but many connections of boosters, such as the Highfield, approximate to it. If a booster is used simply to supply the extra charging volts of a storage battery it is called an "irreversible" battery booster. In this case it is a shunt-wound generator and is driven by a motor fed from the main circuit. If the booster is a series-wound machine it can be made to add or subtract voltage so as to keep the circuit volts constant. In this latter case it must have its field magnets of well-laminated iron so that the voltage generated shall follow quickly the variations of current. Such a booster is called a reversible battery booster. There is an extensive use of boosters, called negative boosters, in traction supply systems to prevent the potential of the return rail from becoming too high relative to the earth and to prevent the flow of current through the earth which does damage to water and gas pipes. The advantage of the three-conductor system is that it effects a saving in copper in the mains for the same supply voltage at the lamp terminals and the same percentage energy loss in the mains. This saving may amount to as much as 62·5%.

Three-conductor direct current supply systems are in common use in which the generators supply current at 440 volts and the lamps and consuming devices on the two sides are worked at 220 volts. This is about the safe limit for domestic supply for lighting.

Alternating Current Systems.—When the generating station is at a considerable distance from the consuming district, or when the consumers are scattered over a large area, then alternating current systems of supply have to be employed, as this admits of transmission at high voltage and reduction to a low voltage for use. The current in this case is generated by machines called alternators and the current flows backwards and forwards in the circuit. The number of complete cycles of current per second is called the frequency and too commonly used frequencies are 50 and 25, but there are large systems of supply in which frequency as low as 15 is used. The alternators can be made to generate at low or high voltage as required and this voltage can be increased or diminished by sending the current through one coil of a static transformer which raises or lowers voltage at the expense of decreasing or increasing the current in a nearly corresponding ratio. A three-phase alternating current system involves a type of alternator which sends out three single-phase currents shifted relatively in phase by 120° with respect to each other. This involves a line comprising three or perhaps four conductors, between each pair of which consuming devices such as lamps or motors can be bridged. To transmit power long distances we must employ high voltage and correspondingly small currents because the section of the copper conductor used and therefore the cost of the line per mile depends upon the current, though the insulation of the line is determined by the voltage.

At this point some information may be given about supply conductors. These are either aerial (or overhead) or underground. The aerial lines are constructed with well-seasoned fir poles impregnated with creosote in the below-ground portion. They may be single poles or multiple poles of A or H shape. For heavy currents high voltage lines they are steel lattice towers 50 to 150 ft. in height tapering upwards and of square or triangular section. These poles or towers carry cross arms to which are attached single or else chains of porcelain insulators according to voltage. The conductors themselves are of hard drawn copper wire and sometimes aluminium or steel-cored aluminium wire. These lines are spaced apart from 2 to 12 ft. according to the voltage used. Single-phase alternating requires a pair of lines and three-phase four lines. At intervals disconnecting switches are placed and essential adjuncts of an aerial line especially in mountainous countries are lightning protectors which consist in some arrangement, generally two horn-shaped iron rods, by which, if lightning strikes the line, the discharge can get to earth over a small gap or through an electrolytic cell, but the line current cannot follow to maintain an electric arc discharge and so short circuit the line or put it to earth. On aerial lines voltages as high as 150,000 or even 250,000 volts are used. The transmission of power by small electric currents and very high voltages raises many practical problems of great difficulty. The high voltage on the line ionizes the air molecules near it and produces on the line a glow discharge called a *corona*. This involves a dissipation of energy which may be at the rate of several kilowatts per mile of overhead line. (For details see *The Electrician*, Oct. 10, 1913, p. 13.)

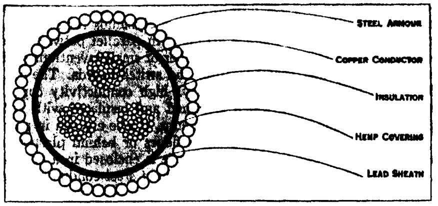

FIG. 2.—SECTION OF TRIPLE CONDUCTOR ARMOURED CABLE, SHOWING THREE COPPER CONDUCTORS SEPARATED BY INSULATING MATERIAL; THE SHEATH IS OF LEAD

Underground Lines.—Underground lines are most usually laid with steel-armoured lead-covered concentric cable (fig. 2). A central core of stranded copper wires or cable is insulated with manilla paper which is impregnated with resinous compounds. Over this is laid a cylindric conductor formed of copper wires and for three-phase cables there may be a second layer of insulation and a third concentric conductor. Then further insulation and a seamless lead covering is laid on. This is protected by impregnated jute or hemp and then an armouring of steel wires or tape is laid on in one or more layers and the whole covered again with hemp. Such a cable can be laid straight in the ground in a trench with only a protective board over it. If, however, the soil is such as to corrode steel or lead, the cable may be laid in a wooden trough and filled in with bitumen. A cable of this kind properly laid may have a life of 30 or 40 years. Concentric cables as above described can be made for voltages up to 60,000 or 70,000 volts. Suitable joint boxes must be put in at intervals to enable tests to be made and faults located. Generally speaking, an underground cable has a capacity of about one-third microfarad per mile. An aerial wire will have very much less capacity but more inductance.

The "capacity effects," as they are termed, associated with long underground cables, call for special means of connecting or disconnecting them in order to avoid the production of electric surges. Electricity flowing in conductors behaves like a very heavy incompressible fluid. It cannot be started into motion instantly and when flowing cannot be arrested suddenly without means for

nullifying its inertia. Long concentric cables must not be switched suddenly on or off the bus bars or switch-boards of alternating current supply stations but the current must be fed into the cables slowly through a variable resistance to avoid sudden pressure rises due to combined capacity and inductance which might break down the cable insulation.

The Swiss Railways.—As examples of typical electric supply for power purposes by alternating currents we may refer to the hydro-electric stations of the national railways in Switzerland. These main-line railways are now operated with single-phase alternating current at a frequency of 16·2/3. For the St. Gotthard line from Basle to Chiasso there are two generating stations, one at Amsteg and the other at Ambri-Piotta on north and south sides of the St. Gotthard pass. These stations are connected by an underground concentric cable. The power is supplied by high level stores of water derived from the river Reuss and from Lake Ritom respectively. This water is led down steel tubes to the hydraulic stations where it is used to drive Pelton turbines direct coupled to single-phase alternators of 13,600 h.p. which generate at a pressure of 15,000 volts. Theoretically, 1 cubic metre of water (or about 216 gal.) in falling down a height of 1 metre or 3¼ ft. can do work equal to 13 h.p. acting for 1 second. Modern turbines can utilize about 80% of the theoretical amount. For these railways stations the voltage of the current is first raised by large static transformers to 60,000 volts for transmission. The two stations together can supply 113,000 h.p. for railway working which is more than sufficient to operate 50 trains simultaneously. The high voltage current is led by overhead lines to various transformer stations where it is reduced to 15,000 volts. The locomotives are equipped with three compensated series alternating current electric-motors, and the current is picked up from an overhead line and returned to the rails or to a third grounded rail.

Two other similar large hydro-electric stations exist in the Rhone valley near and above Martigny to supply the Simplon railway running from Lausanne through the Simplon tunnel to Baveno and Stressa. One station, called the Barbarine station is high up on the Salvan pass and the other is at Vernayaz in the Rhone valley. There is another station at Thusis, near the entrance to the Via Mala, which supplies similarly current to operate the Rhaetic railway which runs from Coire to St. Moritz in the Engadine and to Davos. The electric locomotives on these electric lines are of 1,200 to 2,100 h.p. the latter being able to draw a train of 500 tons up an incline of 1 in 100 at a speed of 40 m. an hour. This electrification of the main lines has greatly increased the average train speed and especially the comfort of working on lines with many long tunnels such as these main Alpine lines. The electric supply lines are duplicated to secure safety and generally follow different routes. The transformers are in iron cases filled with insulating oil and these are placed in the so-called outdoor stations in which transformers and switches are arranged in the open air under a steel lattice framework which supports the insulators and these the connecting bars.

There are in France three-phase alternating current stations in which the alternating current is rectified or converted to a direct current for railway working. The direct current motor has many advantages over the single-phase or three-phase alternating current motor in that the weight per horse power is much less and the arrangements for controlling the speed much more simple. There are practical limits to the voltage which can be used for direct current motors. It is, however, quite a simple matter to build such motors for 1,200 to 2,000 volts. On the other hand the alternating current can be raised in voltage easily by static transformers for transmission and lowered again for use. The practical problem, therefore, which electric traction supply systems involve is that of converting alternating current into direct current. This can be done in one of two ways (i.) by rotary converters and (ii.) by mercury arc rectifiers. The first method uses an alternating current induction motor supplied with three-phase alternating current which is coupled direct to a direct current generator which gives current at 500 volts or 1,200 as required. The direct current is supplied to the motors of the locomotive or of the car by an overhead trolley line or by special side rails, and returned by the main rails. This arrangement is widely used on the urban electric railways in London and other large cities. It involves, however, moving machinery and therefore manual attendance.

Mercury Rectifiers.—The second method by mercury rectifiers is also much used. This depends on the fact discovered by P. Cooper Hewitt that if an exhausted tube has at one end a pool of mercury and at the other end an iron rod, connections to these being made through wires sealed through the tube walls, then such tube has a unilateral conductivity and will allow negative electricity to flow from the mercury cathode to the iron anode but not in the opposite direction. Hence it can rectify an alternating current.

In one form used for railway working the tube consists of a large steel box in which a high vacuum is created by a pump. In the bottom is a pool of mercury which acts as the cathode. In the lid of the box there are six glands through which iron rods pass air-tight and insulated electrically. These rods are connected to the two outer ends of the terminals of the three circuits on a three-phase transformer and the central junction to the mercury cathode. The mercury vapour then acts as a rectifier and converts the three-phase alternating current into a direct current. For further details special treatises must be consulted. (*See* J. A. Fleming, *Mercury Arc Rectifiers and Mercury Vapour Lamps.*)

Public Electric Supply.—The idea of supplying electric current for lighting purposes to a large number of users from a common supply station seems to have occurred about 1878 to St. G. Lane Fox in England and T. A. Edison in the United States (*see* British Patent specifications Nos. 3988 and 5306 of 1878) and was put in practice in New York in 1881, in London in 1882, and by Col. R. E. Crompton in Vienna in 1883–84. The early attempts met with many difficulties and had only a limited range of operation due to the use of a two-wire direct current system with 100–110 volts pressure between the mains. Crompton employed in Vienna a five-wire 440 volt direct current system. J. Hopkinson and T. A. Edison had devised the three-wire system, already explained, in 1883 as a means of extending the range of the direct current system. In 1884–85 S. Z. de Ferranti, who had already invented an alternating current dynamo, patented an improved form of transformer (British Patent No. 15141 of 1885) and soon after developed a system of alternating current supply

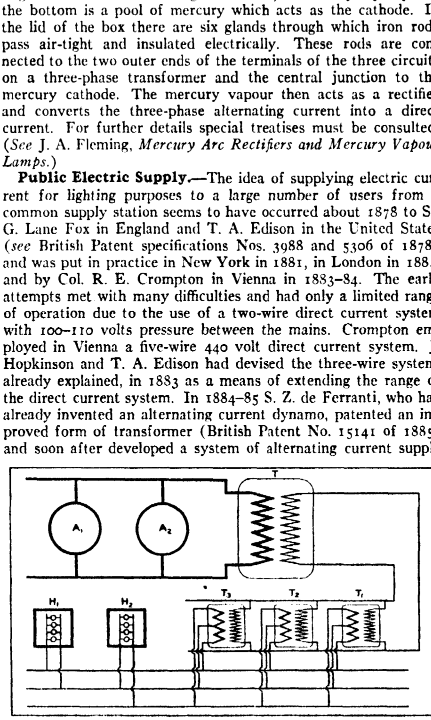

FIG. 3.—SINGLE-PHASE ALTERNATING CURRENT SYSTEM. A_1, A_2 ARE THE ALTERNATORS, PRODUCING A SINGLE-PHASE ALTERNATING CURRENT AT 1,000–10,000 VOLTS; T THE TRANSFORMER; T_1, T_2, T_3 BATTERIES OF ALTERNATING CURRENT TRANSFORMERS, AND H_1, H_2 HOUSES SUPPLIED FROM GENERATING STATION

in which electricity was generated at a high voltage, even 10,000 volts, and transmitted by underground mains to certain transformer stations where it was converted to low pressure and distributed to users at a convenient voltage. Similar systems were devised by Ganz, Westinghouse, Elihu Thomson, Parker and Mordey. S. Z. de Ferranti was unquestionably the pioneer of alternating current high voltage supply. His financial supporters erected a large station at Deptford in 1890–91 for supplying a part of London, and this London Electric Supply Corporation overcame in time many of the early difficulties of such supply

due to capacity effects in the mains and insulation. The alternating current system had great advantages in dealing with an area of scattered users in that the high voltage permitted a small current to convey a considerable amount of power and this demanded only transmission lines of small section. In the early days with the exception of the Ferranti system a very usual voltage of supply on the alternating current system was 2,000 volts on the high

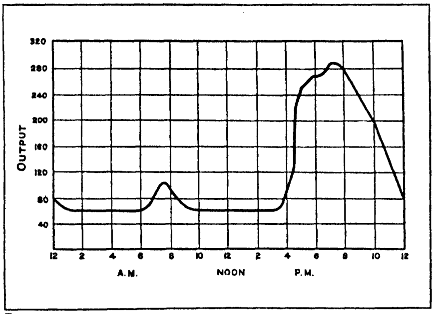

FIG. 4.—GRAPH OF LIGHTING LOAD, SHOWING GREATEST OUTPUT BETWEEN 6 AND 8 P.M., THE SUPPLY BETWEEN THESE TWO HOURS BEING ROUGHLY EQUAL TO THE SUPPLY FOR THE REMAINING 22 HOURS

tension side for generation and transmission reduced to 100 volts by transformers for use in houses.

The three-wire system can also be applied to alternating current supply as well as direct current (fig. 3). Two systems of public electric supply were therefore developed and much put in practice between the years 1882 and 1892 in all parts of the world for public electric supply. One of these was the three-wire direct current system, using dynamos generating at 220 or 440 volts connected across the outer mains, with balancers, boosters and batteries across the two side circuits. This was called the D.C. system, and was found very suitable for the central parts of large towns and thickly populated districts. The other, called the A.C. system, employed alternators and transformers and in country districts overhead high tension mains and distributed to houses at low voltage, 100–110 or 200–220 volts.

The disadvantage of this latter system was that no storage of energy was possible so that the machinery had to be kept running all night to supply the small necessary light, whereas on the D.C. system the batteries delivered the night demand. It soon became clear that in every particular district, whether business, residential, shops or places of amusement, the hourly demand for current followed a certain law which, expressed as a curve plotted in terms of hours of day and night, was called the *load diagram* (fig. 4). If the vertical ordinates of this curve represent kilowatts, the area included between the curve, the end ordinates and the time line is proportional to kilowatt-hours or B.T.U. sent out from the station. The ratio of this total output to the output which would be taken if the maximum demand continued steadily for the whole 24 hours, is called the *load factor*. In a strictly residential district this may be as low as 12 or 15%, but in a shop or theatre district much higher. If, however, there is a demand for power by motors as well as for light the load factor may rise to 45% or 50%.

Electric Meters.—It became clear at a very early stage in public electric supply that electric meters of several different kinds would be required. It is obvious that the consumer most profitable to an electric lighting supply undertaking is not the one who takes the largest supply of electric energy, very irregularly, but the one who takes his supply most uniformly. The former requires the supply station to keep plant ready for action to supply his possible extra demand taken without notice. Accordingly, electric meters were soon devised by numerous inventors of three different kinds. There are, first, meters called ampere-hour meters which measure only the total quantity of electricity passing through them irrespective of the voltage or pressure of supply. These can be designed to read Board of Trade units in kilowatt-hours on the assumption that the supply pressure remains constant. The second type of meter is the watt-hour meter which records the total electric energy which has passed through it irrespective of changes of pressure. A third type of meter is called a maximum demand meter and records the quantity of electricity taken over and above a certain average. It gives an indication of the demand made by the customer on the supply for what is called stand-by plant.

The earliest type of ampere-hour meter was the Edison zinc-sulphate electrolytic meter, but the trouble in reading it caused it to be soon replaced by mechanical meters. These are in effect small electric motors which the current drives round against a certain retarding force which is proportional to the speed. The number of revolutions made by the meter in a given time is recorded on dials like those of a gas meter. If the driving force is proportional to current passing then the dials record quantity of electricity or electric energy on the supposition that the supply voltage is constant. If the driving force is proportional to the electric power passing then the dials record true electric energy in kilowatt-hours. A large number of such motor meters have been invented, such as those by Ferranti, Elihu Thomson, S. Evershed, Chamberlain and Hookham, the Sangamo meter (Edison, Swan Electric company) and others. Some of these, such as the Elihu Thomson motor meter, are suitable both for direct and for alternating current. Others, such as the Schallenberger meter, depend on electro-magnetic repulsion and are only applicable on alternating current circuits. The most usual form of tariff is the flat rate in which the consumer is charged by meter for the units of electric energy actually taken, but owing to the fact that the chief demand for electric supply is for electric lighting and this is determined by the daylight hours and by the customary times for meals and rising and retiring to rest, the lighting supply demand runs up into a sharp peak at certain hours. The object of the various tariffs which have been introduced is therefore to encourage a demand for electric power taken either uniformly, or else at hours when the lighting demand is small for electric cooking, heating, and driving small domestic motors, etc., by giving such supply more cheaply than at the flat lighting rate.

The most common variation on the flat rate is some form of fixed charge depending on the total number of lamps installed and then a charge for electric energy supplied at a much lower than flat rate. (For the various types of tariff in use *see* J. W. Meares, *Electrical Engineering Practice*, ch. xv.)

Extra High Tension National Electric Supply.—The increasing demands for electric energy for power purposes and the numerous and very different supply pressures, voltages and systems have caused great attention to be directed to the problem of national electric supply in Great Britain. Briefly, it is proposed to construct over Great Britain a large system of overhead or aerial conductors consisting probably of steel-cored aluminium cables supported by appropriate insulators on steel lattice towers. The system of supply is to be three-phase alternating current at a frequency of 50 cycles and at a pressure of 132,000 on the main conductors. This system of mains is called the "gridiron" and will have put into it current from selected or constructed stations. From these mains electric current can be tapped off and reduced in pressure by transformers for any required purposes at any place on the route. The "gridiron" will consist of three conductors, one for each phase and doubtless a fourth conductor connecting the neutral points of the three-phase star connected circuits. Special precautions will be taken against the production of steep-fronted electric surges travelling along these lines due to lightning. The gradient of atmospheric electric potential is generally at the rate of 100 or 150 volts per metre, the earth in fine weather being negatively charged. Under thunderclouds, however, the gradient may be many hundred times as great. This means that induced electric static charges are created on an aerial line, and this is, in the old-fashioned language, a "bound" charge. When, however, the thundercloud is discharged by a lightning flash this bound charge becomes free and its potential may be

added at some instant to that of the line. The result may be a flash over at an insulator which for a moment puts the line or one phase of it "to earth," at a certain place. The result is to produce an electric wave of potential which travels away along the line. If the difference of potential between two near points on the line is very large this is called a steep-fronted surge. If such a surge passes back along the supply line into a transformer or alternator it may cause a great difference of potential between adjacent turns of wire and so cause a breakdown of insulation and do damage expensive to repair. Accordingly, many devices have been invented called surge protectors for stopping these steep-fronted surges from travelling along electric supply lines. One of these consists of a peculiar form of electrostatic condenser which is joined across the lines. When a surge comes along it darts into the condenser and expends its energy harmlessly. Another consists of a form of low resistance choking coil with a secondary circuit of non-magnetic iron in which the surge dissipates its energy as heat. (For further details *see* J. A. Fleming, *The Interaction of Scientific Research and Electrical Engineering*, ch. vi., 1927.) Electric feeders or supply lines conveying large currents are always laid in duplicate generally along different routes so that in the event of a breakdown on one line the supply is continued by the other.

Also automatic cut-outs or switches are placed at the ends, operated by relays or electro-magnets, so that in the event of a "dead earth" occurring on one section that faulty section of the line is at once removed from the live circuit. These arrangements generally operate in virtue of the fact that in a line without fault or earth or short circuit the current leaving at the far end is the same as the current entering. If, however, a fault occurs then these currents are unequal and this may be made to actuate sensitive devices called relays which in turn operate the terminal switches and cut out the faulty section of the line.

UNITED STATES

In the United States, systems of electrical conductors within buildings where electricity is utilized are of many different types. Massive structures of fire-resisting construction, industrial and other buildings that are exposed to special fire hazards, and in some cases all buildings within "fire zones" (*i.e.*, the closely built up urban districts subject to conflagration hazards) are ordinarily provided with house-wiring systems where the conductors are drawn into metallic conduits having appropriately heavy fittings at outlets and junctions. Although this system of wiring has the merit of ruggedness, it is expensive, cumbersome, and poorly adapted for future modification or extension, and for this reason the majority of other buildings such as residences, small shops and small or detached structures generally, are equipped with lighter forms of wiring. The principal types of these are the flexible conduit system, where suitably insulated conductors are enclosed in a flexible steel armour composed of a light interlocked spirally-wound steel tape, and a system where suitably insulated conductors are run in concealed spaces upon porcelain insulator supports. The latter is known as the "knob-and-tube" system and is most extensively used. It has been in successful use for a long time, and in many ways it is the most desirable system of wiring from considerations of safety. It has also the advantages of low cost, ease of installation, and great flexibility for future changes and extensions.

The technical aspects of public electricity supply have, in the main, been especially concerned with the production and distribution of electric energy upon a very large scale. The extraordinary growth of the use of electricity, which has resulted, in part, from the steadily declining costs of service and, in part, from the increase in the size and scope of general industrial activity during the past decade, has been reflected in the advance of technical practice. Conversely, the increased efficiency in the use of fuel and the development of high-voltage power transmission over comparatively wide areas have been, to a large extent, the principal factors in lowering the cost of electric service to the public and thus, in turn, in stimulating a demand which has made possible still greater efficiencies of production and distribution. Until a few years ago, the attention of the technicians of the electricity supply enterprises was primarily concerned with the perfection of power-production equipment and with the reduction of the cost of generating energy. The advances in transmission line practice and the wide-spread adoption of the concept of "interconnection" have, however, produced a tendency to build large power-plants at some distances from the centres of consumption and have thus necessitated not only much specialized apparatus for successful delivery of this energy, but also of specialized operating practices.

Concentration of Power.—The larger of the regional schemes for the service of electricity supply represent truly enormous concentrations of power, produced in great volumes at diverse and often remote sources, which must be regulated and controlled so as to meet, at every instant, the constantly varying demands of the consumers. Here there have arisen a host of problems, some of which have successfully been solved by advances in technology, others (up to the present) have only partly been overcome, while still others remain as objectives to reward the skilled research of the future.

The insulation of electric-carrying devices is, in fact, the foundation of the electric power system. While it has been successfully accomplished in the lower range of voltages, very little is still known of its true character or the phenomena involved in its breakdown. The failure of insulation results in the escape of some of the electricity from its intended path and its travel either to ground or to another portion of the energy-carrying circuit. Where the amount of energy involved is large (as is usually the case where many power-plants are tied together in interconnected regional schemes) such a breakdown usually results in the most serious of consequences. A "short circuit" of great magnitude is often produced and this causes an electrical arc which may result in the complete destruction of all the equipment in the immediate vicinity and in the demolition of the buildings which house it. Much attention has, therefore, been devoted to the control and interruption of "short circuits" and to the design and construction of numerous types of protective devices, upon a scale undreamed of a decade ago. Such protective devices consist primarily of the following:—

(*a*) Fuses, of very large size, especially designed to extinguish any electric arc which may arise during their functioning. The usual type is the "expulsion fuse," which consists of a long, thin strip of metal inside a tube made of insulating material and, in some cases, filled with a non-conducting and fire-extinguishing liquid. When the current exceeds a pre-determined point, the metal strip melts and thus breaks the circuit and the resulting gases in the container suddenly expand and are discharged in such a way as to put out the arc formed by the melted fuse.

(*b*) Circuit-breakers, which are practically switches of great size, opening automatically whenever the current exceeds a given amount. They consist, in essence, of contacts between fixed and movable current-carrying parts, which contacts are broken when the mechanism is actuated. The contacts are submerged in oil, which smothers the arc formed when the circuit-breaker is opened. The apparatus is controlled and released by a very delicate device known as a "relay" which trips the opening mechanism as soon as the current through the line exceeds what is considered a safe value. Modern circuit-breakers to interrupt the current of large systems are enormous affairs and their functioning is usually of the order of an explosion. In such cases, their interrupting capac-

ity falls off rapidly with each successive operation unless they are overhauled and put in proper shape after each one. Because of the intensive carbonization of the oil when a heavy arc is formed in it, good practice usually dictates a complete change of oil after each functioning of a circuit breaker on high-voltage systems.

Equipment Problems.—With the growing extent and intricacy of large, interconnected schemes, a very serious problem has arisen in the successful operation of circuit-breakers in such a manner that the failure of one line, or piece of apparatus, will not interrupt service throughout the entire region. While great progress has been made in the design of duplicate equipment and of relays which will automatically isolate the affected portions from the rest of the system, no ideal method has yet been found and much work still remains to be done before this is satisfactorily accomplished. In addition to these details, the very high voltages and the large volumes of energy which are usually encountered have necessitated the design and construction of all usual switches, transformers and various auxiliary devices along lines of great size, strength and ruggedness. As a result, these appliances have attained weights and dimensions which have made their enclosure within buildings a matter of great expense and difficulty. In addition, the increased factor of safety in case of short-circuits (because of the fact that electric arcs or flames resulting from burning oil will travel upward and quickly dissipate themselves into the surrounding atmosphere) has made it much less hazardous to place such apparatus out in the open. An important development of the past decade has thus been the outdoor substation for all high-voltage lines. Such stations usually cover large areas and are laid out with mathematical precision over many acres of ground. The maze of poles, wires and insulators which accompanies an important junction point on a major transmission system is usually termed a "switch-garden."

The extent of the areas covered by most of the regional schemes and the necessity for their direction from one central point have led to the development of operating practices of remarkable scope and authority. Many systems have simultaneously in operation dozens of power-plants, containing literally hundreds of separate machines and connected in numerous places with the lines of other and similar enterprises. The Pacific Gas and Electric Company, for instance, has commonly 32 hydro-electric plants of all types and sizes and three large steam-plants all running at once and all delivering current into a common network of transmission lines. Feeding from these lines are many large sub-stations, where the voltage is lowered to that of the distribution circuits and some of which, in turn, contain further machinery for the regulation, rectification and transformation of the power for railway and special industrial purposes. In addition, current is procured from the great hydro-electric plant of the city of San Francisco and from various mines, mills and irrigation enterprises in the distant mountains, while electricity is exchanged with other systems to the north, east and south. The co-ordinated operation of this gigantic enterprise, with the proper allocation of loads so that the most efficient plants will produce their maximum of output, with the reduction of purchased current to a minimum and with provision for future surpluses or deficiencies of water-power in accordance with the precipitation and run-off of the year, is all accomplished from one central office. One man, sitting at a little desk in front of a huge map, whereon there is displayed every transmission line, every electric generator and, in coloured lights, the position of every principal switch and an indication of whether it is open or closed, directs the operation of the service of electricity supply over an area of more than 30,000 sq.m., or almost that of all England. Contact with nearby plants and stations is accomplished by telephone over the company's own system and the opening and closing of important switches and the starting and stopping of machinery is undertaken upon orders from the chief despatcher in the central office. Communication with the more distant plants, many of which are located some 200 m. away, is effected by what is commonly called the "carrier current" system of telephony, where the actual power-carrying lines of the transmission system serve, in addition, to carry certain modulations of high-frequency electric waves which can be used to convey speech.

Several special devices have been employed with success in the control of smaller hydro-electric plants and substations located in regions which are remote and sometimes difficult of access. One such development is the automatic station, which is supervised by mechanism actuated from the central point of authority. Water-power plants, up to a capacity of 10,000 h.p., are operated in this manner in numerous sections of the country and eliminate, to a large extent, a personnel of considerable size.

Meteorological Factors.—In various parts of the United States, special conditions are encountered which further complicate the functioning of large regional schemes. A characteristic of urban operation in the older cities (such as Boston, New York and Philadelphia) is the heavy demand for service in the late afternoon. The coincidence of the use for light throughout the commercial districts with that of the transportation systems, at a time when the exodus from business areas to the residential sections and suburbs is at its height, produces a "peak" (or period of maximum electrical demand) of great magnitude. Similar "peaks" of equal size are produced at other times of day whenever the temporary darkness of an approaching storm brings forth an immediate and unexpected demand for light. During such periods, the capacity of the enterprise is taxed to its utmost and generating machinery, held in reserve, must suddenly be called upon to go into action at practically a moment's notice. The forecasting of such periods of darkness has been made the subject of much study and large urban systems are usually equipped with storm detectors. Some of these are essentially barometric, while others are devices which are sensitive to unusual electro-static conditions of the atmosphere. By their use, the director of operations (or "load despatcher") receives some forewarning of the oncoming obscurity and has, in this way, a short time in which to marshal his forces to meet the impending lighting demand upon his enterprise. Other meteorological conditions have caused many difficulties and have influenced, to no slight degree, the technology of the wide-spread transmission and distribution of electricity. Two of these of major importance are lightning and sleet. The northern section of the United States, lying east of the Rocky mountains, is subject to frequent and violent atmospheric disturbances and, during the summer months, to thunder-storms of remarkable severity. Transmission lines are very susceptible to lightning, because not only a direct hit damages them, but also a flash in their immediate neighbourhood is sometimes sufficient to set up serious electrical disturbances within the system. Lightning arresters, by means of which the discharge is permitted to reach the ground through a path which the regular electrical current cannot follow, are therefore placed at all stations between the transmission wires and the sub-station apparatus. On some lines an additional wire is placed above all the others at the very top of the transmission line towers, and this wire (connected to "ground") serves, to a considerable extent, to act as a continuous lightning rod. Many parts of the country, especially the North-eastern section and the Central-middle West, are visited, during the winter months, by severe sleet storms. These are the result of peculiar atmospheric conditions, where moisture is precipitated as rain into a region where the temperature is below freezing. A heavy coating of ice soon forms upon all objects and, in the case of electric supply systems, this produces an additional weight which may be very destructive. The strength of insulators and attendant structures must, therefore, be designed with a view towards the successful support, not only of the usual dead weight of the wires, but also of the additional burden of the maximum expected coating of ice, plus the added strain of a heavy gale of wind which may blow against wires whose size is increased by this ice-coating. Based upon observations and past experience, the United States is roughly divided into three zones, where sleet storms of various degrees of severity may be expected to occur and the standards of construction for electrical lines have been determined accordingly. These districts are:—

(a) The "heavy loading" district, lying east of the Rocky mountains and north of the Southern States. Here provision is made

for a coating of ½ in. of ice (in radial thickness) upon all wires, together with a wind pressure of 8 lb. per square foot of surface (which corresponds to an indicated velocity of some 73 m. per hour).

(*b*) The "medium loading" district, comprising the North Pacific coast, the Rocky mountains and a belt approximating the Piedmont region of the Southern States. Provision is made for ¼ in. of ice and the same wind pressures.

(*c*) The "light loading" district, being the balance of the country and embracing the California coast, and the territory along the Mexican border and the Gulf and South Atlantic coasts. Here no sleet may be expected, but provision for 12 lb. wind pressure (an indicated velocity of 92 m. per hour) is made.

Actual conditions throughout the country, together with proper design to withstand weights of ice even greater than the above, are still the subjects of much study and experimentation. An interesting method for the prevention of sleet has been successfully adopted by several Eastern regional schemes. This consists of the discontinuance of the transmission line as a carrier of the usual high-voltage energy and the transfer, through it, of considerable current at very low voltages at recurring periods ranging from 30 min. to an hour. This heats the wires to an extent which inhibits the formation of ice upon them. This scheme is, however, practicable only where a large number of circuits are available, so that the several wires may be kept hot, in rotation, without making it necessary to discontinue service on the entire system.

High-tension Underground Cable.—An important development of high-voltage transmission has been the successful design of the high-tension underground cable, which avoids not only all troubles arising from lightning and sleet but also makes possible the transmission of energy through districts where the density of population or the expense of the land necessary for a right-of-way would render the installation of overhead wires impossible. Cables of this kind usually consist of one single conductor made up of a core of several strands of copper wire and wrapped around with many layers of paper impregnated with a mineral insulating material. This, in turn, is covered with a heavy lead sheath. Such a cable, carrying 132,000 volts, was put in operation in the city of Chicago by the Commonwealth Edison Company late in 1927. The insulation consists of paper $\frac{11}{16}$ in. thick and the outside diameter of the complete cable is 3·1 inches. A peculiarity of this cable is its hollow centre, through which oil is forced under pressure and which assists not only in preventing excessive heating, but also in maintaining the insulating qualities of the paper wrapping. At high voltages in the usual three-wire alternating current practice, three such cables must, of course, be used for each electrical circuit and commonly occupy three separate ducts throughout the underground system. At regular intervals manholes of large dimensions are provided for the splicing of the various lengths of cables and for their ventilation, inspection and repair.

ELECTRICITY TRANSMISSION: *see* Electrical Power Transmission.

ELECTRIC LAMPS AND VALVES, MANUFACTURE OF. The history of the incandescent lamp has centred mainly round improvements in the filament. In the first practical lamps (produced independently by T. A. Edison and J. W. Swan between 1878 and 1880), carbon filaments were used, and carbon had no real rival until the appearance first of the Osmium lamp (1898) and then of the Tantalum lamp (1903). By 1904 Tungsten had begun to establish itself as the most suitable filament material, and although there was one fundamental improvement in its manufacture (the change from the squirted filament to the drawn wire which began in 1906), its supremacy has not so far been challenged.

Side by side with this improvement in the filament, there has gone improvement in the manufacture of the whole lamp. The earlier lamps were hand made; gradually automatic methods have been developed, and the cost has fallen progressively while the performance of the lamp has improved.

By 1927 the total world consumption of electric lamps had reached a figure of 950 millions per annum, and manufacture on this scale is inevitably conducted on lines of specialized mass production. Now it is not within the scope of this article to discuss the methods of mass-production—they are mainly matters of organisation,—but it is relevant to explain that the success of mass-production depends largely on a knowledge of the scientific principles underlying its processes and products. In what follows, therefore, these principles are explained in detail in their relation to the actual methods and materials used in the manufacture of lamps.

The Principles of Lamp Design.—Let us first consider what happens when a filament is heated in a vacuum. The whole of the energy supplied to the filament is radiated in the form either of heat or light (except for that negligible amount conducted away by the filament leads). The proportion of the energy which is radiated as light increases with the temperature, and it is therefore the aim of the lamp maker to arrange that the filament temperature shall be as high as possible consistent with a reasonable life (in practice 1,000 hours is accepted).

The first essential, then, is to find the filament material which can best stand these conditions, and tungsten, with its exceptionally high melting point (3,380° C) is the outstanding material for the purpose.

The limiting temperature in practice is far below the melting point of the filament; long before that temperature is reached other factors come into play which tend to shorten the life of the filament; these are evaporation of the metal (which both thins the filament and obscures the glass bulb), and loss of mechanical strength. Of these, evaporation is the more important, and for a life of 1,000 hours, it sets a practical limit of about 2,100° C to the temperature at which a tungsten filament may be maintained in a vacuum. (Carbon has an even higher melting point than tungsten, but it fails at a much lower temperature through disintegration.)

The use of a vacuum has this advantage, that the only loss of energy from the filament is by radiation. On the other hand, if the filament is surrounded by an inert gas (*i.e.*, one which will not attack it chemically), its temperature can be raised considerably higher than is possible in a vacuum before the loss of tungsten by evaporation becomes serious. It is true that the vapour pressure of the tungsten has gone up with the temperature, but in spite of this, evaporation is suppressed by the surrounding gas, the molecules of which prevent the tungsten molecules from leaving the filament permanently as freely as they otherwise would. But this is not the whole story. The use of a gaseous atmosphere instead of a vacuum allows the temperature of the filament to be raised, but at the same time in addition to the heat wasted by radiation, a certain amount is now carried away by conduction and convection.

These terms require some explanation. Heat carried by conduction is passed on from molecule to molecule of the gas, just as happens in a solid. Convection on the other hand is the transfer of heat by moving streams of gas. The gas near the filament becomes heated by conduction; its density decreases and it rises, cool gas taking its place. The hot gas goes on rising till it reaches the walls of the bulb, where it is cooled, and sinks again till it reaches the filament; thus a continuous cycle is set up, which is termed convection.

Now in general the amount of heat carried away from a hot body by a gaseous atmosphere is proportional to its surface area; but in the case of a thin filament the statement requires qualification. Langmuir showed that any hot body in a gas is surrounded by a stagnant layer of gas; heat passes through this layer by conduction and is then carried away from its surface mainly by convection. It is therefore the surface area of this gas layer, and not of the solid body itself which determines the amount of heat lost.

Applying this knowledge to the case of a filament, it is found

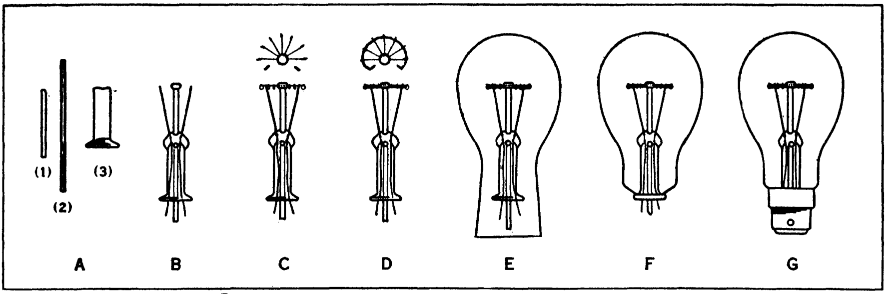

FIG. 1.—DIAGRAMS ILLUSTRATING THE ASSEMBLY OF AN ELECTRIC LAMP
A. (1) Glass rod; (2) glass exhaust tube; (3) glass tube flanged on an automatic machine. B. The parts shown in (A) have been assembled and sealed together, with the lead-in wires in place. A small hole will be seen in the "pinch" through which the exhaust tube ultimately connects with the inside of the bulb. C. Molybdenum support wires have been inserted and bent to shape. D. The filament has been placed in position. E. The bulb is ready for "sealing-in." F. After sealing-in, the bulb has been exhausted (or filled with gas, as the case may be) and the exhaust tube sealed off. G. The finished and capped lamp

that the thickness of the stagnant gas layer, which is independent of the diameter of the filament, is very large compared with the diameter for ordinary sizes of lamp, so that for thin filaments the advantage of the extra temperature attainable in a gaseous atmosphere is more than offset by the greater convection losses. The use of thick filaments is in most cases not practicable, as they are suitable only for very large currents, but it was found that a thin filament coiled into a close spiral behaves, so far as convection losses are concerned, almost exactly like a solid filament of the same diameter as the spiral, while the spiral form allows the wire to be long enough to have the necessary electrical resistance. It thus becomes possible to use a gas to cut down the evaporation of the filament and at the same time to obtain the increased efficiency due to the higher temperature.

This then is the principle on which the so-called "gasfilled" lamp depends. In order to make fullest use of it, the right gas must be chosen. For all but the largest sizes of lamp, argon (mixed with a little nitrogen) is used. Argon is chosen because it is chemically inactive, and being a heavy gas it carries away less heat from the filament than would a lighter gas. The nitrogen is added to lessen the tendency for discharges to take place in the gas at the higher voltages. In the very largest lamps argon shows no advantage in efficiency over nitrogen, but as the latter re-acts slightly with tungsten, the argon-nitrogen mixture is frequently preferred even for large lamps in spite of its increased cost.

The Rating of Lamps.—Lamps are classified according to the voltage on which they are intended to run, and are rated in watts (the watt is the electrical unit of power and equals $\frac{1}{746}$ horse power). The ratings of lamps for use on supply mains range from about 15 watts to 1,500 watts. Smaller lamps (*e.g.*, motor car lamps, flash lamps and so on), and larger lamps (*e.g.*, lighthouse lamps and cinema studio lamps) are also made.

The light given by electric lamps is measured in lumens (a lumen is equal approximately to eight-hundredths of the intensity of the light emitted by a uniform source of one candle power. *See* article on "Photometry"), and the "efficiency" of a lamp is measured in lumens per watt. This efficiency is, as previously explained, dependent on the filament temperature, and it can always be increased (up to the melting point of tungsten) at the sacrifice of life.

It is therefore necessary to decide on a suitable life, and arrange for the filament to run at the temperature (and therefore efficiency) which will give that life. It has been found in practice that the most economical life is about one thousand hours, and this figure has therefore been taken as the standard.

The size of the lamp introduces another factor. Lamps of large wattage can, owing to their thicker filaments and for other reasons, run at higher efficiencies than smaller lamps, and in practice the efficiency of lamps for a thousand-hour life range from 8 lumens per watt for the smallest lamps to 20 lumens per watt for the largest.

One of the biggest difficulties encountered in fixing the suitable ratings of lamps is the fluctuating voltage which occurs in most electric supplies. Every lamp made is marked with its rating in watts and the voltage for which it is designed. Unfortunately, the rate at which life (and efficiency) changes with changes in voltage is very high, as the following table shows.

TABLE I.

The figures below are typical, and refer to a 220 volt 100 watt gas-filled lamp, *i.e.*, a lamp designed to consume 100 watts on a 220 volt circuit, and to live 1,000 hours. Corresponding to the voltage changes in column (a) are given the corresponding changes in watts consumed, light emitted, efficiency and life. All of these are expressed as *percentages* of the nominal or rated figures.

(a) Percentage of nominal volts	(b) Percentage of nominal watts	(c) Percentage of nominal lumens	(d) Percentage of nominal efficiency	(e) Percentage of nominal life
90	85	69	81	437
95	93	83	89	226
100	100	100	100	100
105	108	118	109	55
110	116	138	119	30

Thus if a lamp is correctly designed to have a life of 1,000 hours at the declared voltage of the electricity supply, its actual life will be 600 or 2,000 hours according as the supply voltage is 4% high or 4% low.

Another difficulty is the existence of electricity supplies of many different voltages in different districts; its effect is, of course, to multiply unnecessarily the number of types of lamp which need to be manufactured. There is, however, a strong movement towards standardisation, which, fairly complete in U.S.A., is making great progress in Great Britain, but less in the rest of Europe.

The Materials and Processes of Manufacture. *Glass Work and Assembly of the Lamp.*—The first components to be considered are the glass parts—the bulb, the tubing and the rod. It is not proposed to describe in very great detail the manufacture of these, as the technique involved is for the most part that usually followed in the large scale manufacture of blown glass articles. It is however necessary to explain the reasons which determine the choice of the particular types of glass used, as they are of interest not only in themselves but as illustrations of important principles in mass production.

The bulbs are made of a "crown" or lime-soda glass, largely because this type of glass has a shorter working range than a lead glass, that is to say it remains soft over a shorter range of temperature. This property suits the automatic type of machines used for blowing bulbs and for sealing the bulb on to the internal glass

work. On the other hand, the same glass cannot be used for the internal part of the lamp, for electrical reasons. Glass is a good insulator at ordinary temperatures, but when heated it gradually becomes a conductor, and moreover conducts electrolytically so that in the case of a soda glass metallic sodium would be liberated in quantities sufficient to upset the working of the lamp. Lead glass does not cause this trouble—if it does electrolyse, the product is lead, which is inoffensive—and therefore lead glass has to be used for the "pinch" (*see* figure 1 [b]) and for the studs which carry the support wires.

At the same time, there must be constancy of composition from day to day. A skilled glass blower blowing bulbs or assembling lamps by hand can vary conditions to suit the glass as he gets it; automatic machines cannot do this without resetting; and if this is required too frequently the machines cease to be automatic. A further factor necessitating constancy of composition is that the lead-in wires which carry the current to the filament have to be sealed through the glass, and therefore the coefficient of expansion of the glass must be kept closely within the limits which suit the wires used.

The lime-soda glass used for the bulbs is melted in tank furnaces having a capacity of about 80 tons. The blowing of the bulbs is entirely automatic; the "gathering" of the necessary amount of glass for one bulb is done by suction applied through a long arm which dips momentarily into the tank and then transfers the glass to a mould in which it is blown by compressed air into the correct shape. Even the cutting off of the surplus glass at the neck is done automatically.

The glass tubing and rod used in the internal structure of the lamp is also made by machine; in this case the molten glass is fed continuously on to a rotating mandrel (hollow in the case of tube, solid for rod) from which it is as continuously drawn off in the state of finished tube.

The sequence of operations in the assembly of a lamp ready for pumping is shown in figure 1, which is mainly self explanatory. Two points only need further mention. The lead-in wires are made of a nickel-iron alloy, copper plated and then covered with potassium borate. The composition of the alloy and the thickness of the copper coating are so adjusted that the composite wire has approximately the same coefficient of expansion as the glass. The borate coating is added to allow the glass when melted to "wet" the wire and make a gas-tight seal.

The support wires are made of molybdenum, a metal of very high melting point (2,600° C). The molybdenum wire is made by a process similar to that described later for the tungsten filament; it is used in preference to tungsten for the supports because its mechanical properties make it more suitable.

Evacuation.—The next stage after assembling the electric lamp is to evacuate it; this applies equally to vacuum and gas-filled lamps, but the technique and the reasons behind it, although over-lapping somewhat, are not quite the same in the two cases. In each case the chief difficulty to be overcome is the removal of the gas which is occluded on the bulb walls and other internal surfaces of the lamp, rather than the air which is "free" in the bulb. ("Occlusion" is a term used rather loosely to describe the state in which gases are held either in the body of a solid or on its surface. The theoretical aspects of the subject are too complex to discuss here; for all practical purposes it is enough to picture glass or metals holding gases in solution as water dissolves air.) Dealing with vacuum lamps first, the occluded gas is freed from the walls by heating the bulb to about 400° C during the pumping process.

This process is carried out on automatic machines consisting roughly of a turntable rotating step by step, the hollow stems of the lamps being inserted in suitable holders. As the machine rotates, these are connected successively with suitable vacuum pumps. It is not, however, practicable on a mass production scale to pump each lamp by mechanical means to the required vacuum, which is of the order of 0·0001 mm. mercury. On the other hand, if the residual pressure is much greater (*i.e.*, anywhere between ·005 and 1 mm.) destructive discharges are liable to take place in the bulb.

The necessary high vacuum is therefore produced by physico-chemical means after the lamp has been sealed off from the pump. The usual method is to apply to the filament, before mounting, a thin coat of red phosphorus mixed with a binder and an additional material such as cryolite or another fluoride. (The action of the cryolite is to keep as transparent as possible the film formed on the inside surface of the bulb.) The whole mixture is known as a "getter."

When the lamp has been sealed off from the pump the operation termed the "clean-up" is carried out, during which the getter fulfils its function of completing the evacuation to the necessary high degree. In this operation the lamp is connected in series with a suitable resistance (to protect the lamp from the passage of destructive space-currents) and the filament is then heated, first to a fairly low temperature to volatilize the phosphorus (actually about 90% of its rated voltage is used) and then to a higher temperature than it normally attains in its life (about 110% of its normal voltage). During these stages the clean-up takes place. Finally the lamp is burnt for a short time at 110% of its rated voltage without the protection of a series resistance; this serving to test finally that the lamp has cleaned up, and also to bring the filament to a stable condition which it will maintain during its life. The above described series of operations is carried out on an automatic machine analogous in principle to the pumping machine: The turntable in this case carries lamp holders which are connected at each successive step to the appropriate electric circuits.

The exact mechanism of the clean-up is not fully known, but the following may be taken as a fairly exact picture of what happens. When the filament is first lighted up, the phosphorus vaporises, and then condenses as red phosphorus on the inside walls of the bulb. At the same time a great proportion of the gas molecules go down on the bulb surface and are held there, mixed up with the phosphorus layer. But while this is going on, violent ionization of the gas is occurring, as a result of which the phosphorus already on the glass is subjected to electronic bombardment.

This bombardment re-converts some of the phosphorus to the white variety which vaporises and recondenses again as red phosphorus, burying more gas molecules and presenting a fresh surface to which still more gas can attach itself. The process is mainly completed in a few seconds, but it can continue so long as there is any electronic bombardment of the surface. If, therefore, any gas tends to be freed during the life of the lamp, the clean-up will recommence on a smaller scale. Thus a vacuum lamp carries throughout life its own automatic device for dealing with any traces of gas liberated, before they can become harmful.

There is only one limitation to the use of "getters" in vacuum lamps, and that is that the voltage must be higher than the ionisation potential of the gases and vapours present; in practice it must be well above this figure, and "getters" cannot satisfactorily be used in lamps working at less than 50 volts.

Capping.—After pumping the lamp is capped. The cap shells are stamped out of sheet brass, placed in position in a mould together with the contacts; liquid black glass is run into the shell and pressed into shape by a plunger to form the base of the cap.

After capping, the lamp is tested, and it remains only to stamp the bulb and wrap the finished lamp.

Gasfilled Lamps.—The process just described for the removal of traces of residual gas by means of "getters" does not apply to gasfilled lamps. In this case it is equally if not more important to remove all traces of residual gas and vapours before filling the bulb with inert gas. This is usually accomplished by evacuating to as low a pressure as possible with all the glass work hot, and then washing out the bulb several times with pure dry nitrogen before the final filling takes place. The purification of this nitrogen, and also of the gas (argon or nitrogen) actually used for the filling requires to be very carefully carried out; elaborate chemical methods of purification being used to remove all traces of oxygen, carbon dioxide, and water vapour. Of these, water vapour is the actively dangerous impurity, the others are harmful because they readily form water vapour with any traces of hydrogen

present (and the metal work can always supply these).

Very small amounts of water vapour can seriously shorten the life of a gasfilled lamp; this is due to a cyclic action in which the water vapour acts as a catalyst. The mechanism of the action is worth describing in some detail, because water vapour attack was, and to some extent still is, one of the most difficult problems to overcome in the manufacture of gasfilled lamps Briefly, the water vapour attacks the hot filament forming hydrogen and tungsten oxide; the latter volatilises and leaves the spot where it was formed. Its rate of travel through the stagnant layer of gas round the filament is however very slow, and by the time it has travelled a short distance away it has cooled enough for the reverse action to take place; *i.e.*, metallic tungsten is again formed, together with water vapour, the latter being free to start a new cycle. The tungsten usually finds its way to an adjoining part of the filament, where it builds up a thick patch. The action is cumulative since the hot spot first attacked tends to become thinner and therefore hotter, so stimulating the attack. The only preventive is very careful pumping—great care in drying and purification of the wash-out and filling gases and extreme cleanliness of metal parts. The clean-up method is useless because of the presence of a gaseous atmosphere, nevertheless phosphorus is frequently used as it can combine chemically with traces of free oxygen.

The Manufacture of the Tungsten Filament.—Although metallic tungsten can be liberated fairly easily from its ores, the high melting point of the metal has necessitated the development of quite special methods for its conversion into wires and other usable forms. The earliest tungsten filaments were made from tungsten powder by mixing it with a binder into a paste which was squirted through dies; the binder was afterwards burnt off leaving a coherent but fragile filament. The squirted filament was superseded by drawn tungsten wire.

The first step is to produce a pure tungstic oxide, which is reduced in hydrogen leaving tungsten in the form of a fine powder. The powder is pressed hydraulically into rectangular "slugs" which may be anything from 8 in. to 12 in. long and from ¼ in. to ½ in. square; these on removal from the mould are just strong enough to be handled. The slugs are hardened by heating in a hydrogen atmosphere to about 1,200° C, and then "sintered" by the passage of a current great enough to bring them to nearly 3,000° C (400° below the melting point). During the sintering process the grains of metal powder grow together, and the sintered slug or ingot has a coarse crystalline structure.

The size of the grain can be controlled by many factors such as the fineness of the original oxide, and of the tungsten powder, also the temperature and time of sintering, and can vary between a microscopically fine structure and one so coarse that the whole ingot may consist of a few large crystals. At this stage, however, the individual crystals are not the homogeneous close-packed molecular lattices usually associated with crystal structure; under the microscope voids are visible, and the density of the ingot is only 17–18 as compared with 19·32 for a perfect tungsten crystal.

The ingot is next "swaged"—an operation consisting in hammering the heated ingot by means of a pair of rapid-acting mechanical hammers. The swaging operation is repeated many times, the hammer clearance being gradually reduced as the ingot becomes a thin rod; the swaging temperature is also reduced progressively from 1,500° C heat to a dull red (about 900° C). The final product of swaging is a rod about 0·75 mm. (3½ in.) in diameter; the metal has been consolidated and at the same time the crystal axes have been elongated in the direction of the axis of the rod giving a fibrous structure.

The thin rod is now strong enough to be drawn through dies. The drawing process is similar to that normally employed for other metals; the main difference is that the wire is heated to a temperature which gradually falls from about 1,000° C to 600° C as the diameter decreases; the dies are made of diamond or similarly hard material and are kept heated. As the drawing progresses the metal becomes increasingly ductile, in which respect it appears to differ from other metals, which if drawn without annealing become harder. The structure of the finished wire is in effect a bundle of fine elongated crystalline threads.

The spirals used in gasfilled lamps and in some vacuum lamps are made by coiling the wire on a mandrel from 3 to 7 times the diameter of the filament, the spaces between the turns being about ⅓ to ½ of the diameter of the wire itself. The coils are made on automatic machines in continuous lengths, the mandrels being removed by solution in acid. As a matter of interest, the following figures of wire size are given. The filament of a 240 volt 15 watt vacuum lamp has a diameter of 0·015 mm., that of a 240 volt 60 watt gasfilled lamp has a diameter of ·030 mm. for the actual wire, the diameter of the spiral being 0·21 mm. approximately. Its length is 56 mm. while the total length of filament wire used is approximately 900 mm.

The Behaviour of the Filament in the Lamp.—In the case of the straight filament vacuum lamp, when the filament is heated the fine crystals begin to grow in size and diminish in number by mutual absorption, and after a short time the filament consists of a relatively small number of large crystals many of which extend right across its width. This process of growth by absorption continues during the life of the lamp, and after some time the boundaries between pairs of crystals may stretch across the filament. Failure of the filament may take place by lateral slip of the crystals at such boundaries, or by thinning of individual crystals, either by viscous flow or by evaporation.

All of these types of failure have been studied experimentally, and the efficiencies of lamps have been fixed at such figures that such failures shall not normally occur during the standard life of the lamp. Incidentally, failure by slip at the boundaries can be controlled to some extent by the addition of traces of other materials to the tungsten before it is made into wire; this question is more fully discussed below in connection with coiled filaments for gasfilled lamps.

In the case of the gasfilled lamp, the problem is a different one. The spiral filament is arranged as a flat wreath (in small lamps) or in a series of V's (in large lamps). The spiral is not under tension, but hangs freely under its own weight. Now when crystal growth takes place in such a filament, there is a tendency for the spiral to open out and sag. This opening of the spiral allows of excessive cooling of the wire by the gas stream, and if continued, results in a serious loss in efficiency. (The reasons for this have been explained above under "Principles of Lamp Design.")

Much experimental work has been done with a view to developing a filament which shall not sag appreciably. The earliest method used was to add about 0·5% of thoria to the tungstic oxide from which the metal powder was made: in the finished wire the thoria segregates in the grain boundaries and hinders grain growth and therefore sagging of the spiral. This slowing of the grain growth was only partly successful, and the problem was attacked from another angle; instead of slowing the growth it was accelerated so as to be finished within the first second of heating the filament, thus giving the filament no time to sag appreciably.

Curiously enough, this end can be achieved in two entirely different ways. One is to add thoria as before, but with an alkali salt such as sodium or potassium chloride in addition. The other is to add to the tungsten a small amount of silica and an alkali salt (such as sodium chloride). In this case the additives do not remain in the finished wire; apparently they boil out during the sintering process carrying away other impurities, and leaving the tungsten purer than it can be obtained without their use.

When spiral filaments made of such metals as these are burnt, very rapid grain growth ensues, and within a second or so, whole turns of the spiral, and in some cases many consecutive turns are found to consist of single crystals. Moreover, the orientation of these crystals is such that their axes do not follow the convolutions of the spiral, but are parallel to its axis; that is, the structure is such as would be obtained by carving the coils out of a solid crystal. This condition is conducive to the maximum stability, and no further molecular rearrangement takes place during life so that sag is practically eliminated.

No comprehensive theory has yet been established to explain this phenomenon of rapid crystal growth in coiled filaments.

Special Types of Lamps.—The processes of manufacture just described are those characteristic of what might be termed the

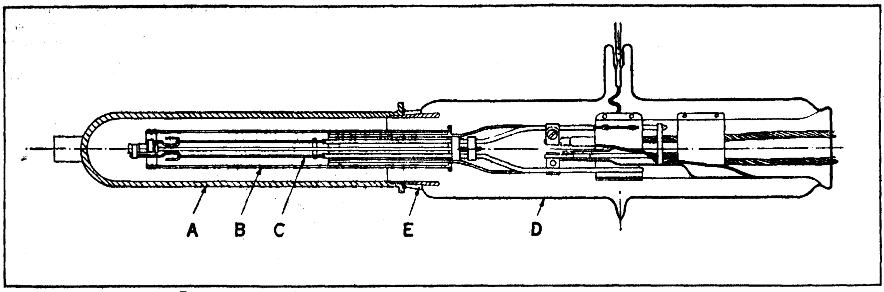

FIG. 2.—DIAGRAMMATIC SKETCH OF A SECTION OF A TYPICAL COOLED-ANODE VALVE
A. the copper anode. B. a grid of molybdenum wire woven on a braiding machine. C. the tungsten filament. D. the glass envelope. E. a thin nickel iron sleeve joining the glass to the copper anode

common type of lamp, that is to say, those which run off ordinary supply mains, with ratings between 15 and 1,500 watts. Besides these there are of course the various kinds of low voltage lamps, of which those used in motor-cars and pocket torches are typical, and very large lamps such as are used in lighthouses and aerodromes. Figure 2 shows these two extremes compared with an ordinary lamp.

The principles involved in the manufacture in the case of the small low voltage lamps are essentially the same as have been already described; certain difficulties arise in matters of detail. Gettering, for instance, is not applicable for the reasons already mentioned. Again a very short filament suffers unduly from the disproportionate cooling of its ends by the supports, so making it necessary that the rest of the filament shall run at a correspondingly higher temperature to give a reasonable efficiency.

The very large lamp differs in another respect; the number required being comparatively small, mass production methods are not applicable, and the construction becomes a matter of skilled craftsmanship rather than of machine design.

The Testing of Lamps.—To complete the account of lamp manufacture it is necessary to mention very briefly the checks imposed on the quality of the product. The two important tests are those for uniformity of manufacture and for quality of the lamp.

In the *Rating Test* for uniformity of manufacture, the lamps are burnt at the rated volts marked on them, and their consumption in watts and efficiency in lumens per watt are observed. These must fall within definite limits laid down in standard specifications.

Life Tests are naturally carried out on only a small proportion of the lamps made. The lamps so tested are always burnt at the efficiency (lumens per watt) for which they were designed; this is arranged either by selecting lamps found to be very exactly rated or by adjusting the voltage slightly to give the correct efficiency. The lamps are run to extinction, the candle power being measured at regular intervals. The average performance called for is a life of 1,000 hours with an average candle and efficiency maintenance of not less than 90%.

THERMIONIC VALVES

The term "thermionic valve" is a very wide one, covering a field which ranges from the smallest amplifiers and detectors used in radio reception to mercury vapour rectifiers handling hundreds of kilowatts. It is proposed only to discuss those valves which depend for their operation on the use of a heated filament.

In general, the technique of large-scale manufacture of such valves has been based almost entirely on that of lamps, which had reached the mass production scale while the valve was in its infancy.

Owing to the extreme rapidity with which the use and development of valves has grown (mainly due to broadcasting), there has not yet been time for the manufacture to settle down on the standardised lines reached in the case of lamps, but the general principles are sufficiently clear to enable a fairly accurate picture to be drawn.

The Filament.—As in the case of the lamp, the filament is the crux of the problem, but the problem is different. In each case the filament is heated by a current, but while the lamp filament has to emit radiant energy, the valve filament has to emit electrons. Electron emission, like energy emission, increases with the temperature, and the same difficulty arises—that as the temperature is pushed up to increase the emission, the life of the filament is shortened by evaporation.

It should be explained at once that three types of filament are in common use. Plain tungsten is used in large transmitting valves, and in the nearly obsolete "bright-emitting" receiving valves. Most receiving valves have filaments of the kind known as "dull-emitters," the active emitting material being not the metal of the filament itself, but a surface layer of some other material which emits electrons more readily.

Two distinct types of dull-emitting filament are in use, one using thorium as the active material, and the other barium or similar alkaline earths. The thorium dull-emitting filament is made from a tungsten wire containing about 1% of thoria (the manufacturing processes are similar to those described for lamp filaments).

The dull-emitting property is developed, after the valve has been evacuated, by heating the filament to 2,600° C for 1 minute, then to 1,900° C for 5 minutes. In the first heating, some of the thoria is reduced by the tungsten to metallic thorium; during the second stage, thorium diffuses through the tungsten and forms a layer on the surface. This thorium surface has a lower resistance to the passage of electrons than a surface of tungsten; so that at a temperature of 1,600° C the emission is equivalent to that of a plain tungsten filament at 2,200° C. The layer of thorium atoms is continuously renewed by diffusion through the tungsten.

The other type of dull-emitting filament is a modern development of the Wehnelt cathode. This filament has a core of pure tungsten or nickel or one of the platinum metals, and the emitting surface is a coating of an alkaline earth oxide, usually barium or strontium (or a mixture of the two). In the manufacture of filaments, the coating is applied either mechanically before mounting the filament or by chemical action inside the valve. This third type of filament emits at even lower temperatures than thoriated tungsten, with consequent improvement in current consumption. A comparison of relative emissions of the three kinds of filament at their normal operating temperatures is interesting. The emissions in milliamperes per watt of heating current are respectively 5, 30 and 100 for plain tungsten, thoriated tungsten and coated filaments.

Valves with Indirectly Heated Cathodes.—In these valves a tungsten filament is employed, not as an emitter of electrons, but as a heater for a nickel tube covered with alkaline earth oxides which acts as a cathode. Their purpose is to eliminate the hum caused by the use of an alternating supply for the heating current.

The methods of manufacture are in general similar to those already described.

Evacuation.—This is an even more complex manufacturing problem with valves than with lamps. In the first place, the valve contains much more metal work than the lamp, and this has to be freed from occluded gas. Most of the gas can be removed by preheating all metal parts *in vacuo* before assembly; the surface gas can then be dealt with either by bombarding to make the anode hot during the pumping operation (in large valves) or by getters (in receiving valves). The getter generally used in receiving valves is metallic magnesium, a small piece of which is fixed on to some metal part of the valve before assembly, and after pumping is volatilized. This is done by enveloping the valve for a short time in a coil carrying a high frequency current, which by induction causes eddy-currents in the metal parts, so heating them to the necessary temperature.

The reasons which make an extra high vacuum necessary are twofold. In the case of large transmitting valves with plain tungsten filaments, traces of gas cause wastage of the filament by bombardment and also affect the operation of the valve, while in the case of receiving valves the dull-emitting properties of the filament are rapidly destroyed by the minutest traces of oxygen or other electro-negative gases.

GENERAL CONSTRUCTION OF VALVES

Receiving valves such as are used for broadcast reception are made by methods recalling those described for lamps. The glass problem is a similar one. The inside construction is more complicated, owing to the multiplicity of parts, and very exact work is necessary to ensure that correct clearances are maintained between the filament, grid and anode. This is, in fact, a special problem of valve manufacture, and has no analogue in the case of lamps. Grids for these valves are made in continuous lengths by machines which wind molybdenum wire spirally on to nickel supports and automatically spot-weld each turn on to the support. The anodes are of sheet nickel.

Transmitting Valves.—Up to about 2 kilowatts, the construction of these is similar in principle to that of receiving valves, but being much larger and required only in small numbers they are mainly hand-made. Evacuation is carried out without getters, pumping being continued for a matter of hours, while the anode is freed from gas by vigorous high tension bombardment which raises it to a high temperature (1,200°–1,600° C). The anodes are made of nickel, molybdenum or tantalum.

Cooled Anode Valves.—In the transmitting valves just mentioned, the anodes become heated during operation, and this heat has to be dissipated by radiation. The difficulties so caused in the design of valves for handling very large powers led to the development of a radically different type, in which the anode itself becomes part of the envelope of the valve, and can be cooled by the circulation of water or oil through a "jacket" fixed round it. Figure 3 shows diagrammatically a section through such a valve. Figure 4 is an actual X-ray photograph showing the grid and filament system inside a copper anode. Perhaps the most interesting part of the construction is the joint between the anode and the glass envelope. This takes various forms; in the original one a thin copper sleeve was sealed on to the glass and brazed at the other end to a copper anode; the sleeve was made so thin that it could "give" enough to allow for the difference of expansion between itself and the glass. Another method using copper anodes is to make the sleeve of a nickel-iron alloy having the same coefficient of expansion as the lead glass used; to ensure proper welding of the nickel-iron on the melted glass it is copper plated and covered with borax. In a third kind of seal soda glass is used, and the anode is made of a chromium-iron alloy of the same coefficient of expansion as the glass. In this case no plating is required, the alloy itself welding easily with the glass.

A few figures may be quoted to give some idea of the size these valves have reached. Transmitting valves are made having an input of 15 kw.; the waste energy taken away in the cooling water reaches about 5 kw.; the filament has a diameter of 1 mm., and requires a current of 50 amp. at 20 volts to heat it.

And with evolution in size there has gone an even more striking evolution in appearance. That characteristic feature, the bulb, has dwindled to a mere appendage, and the transmitting valve, ceasing to be an example of the glass-blowers art, has become an elaborate engineering structure incorporating a small glass insulator.

ELECTRIC TRACTION. Although experimental electric motors were built nearly a century ago electric traction is a modern development. Briefly described, an electric railway is a combination of a source of electric energy, means for transmitting it to vehicles along a right of way, including the raising and lowering of electrical pressures and conversion of type of current, and motors on the several vehicles provided with means for collecting and controllably converting the energy received into mechanical power.

Early History.—The electric industry, so far as dependent upon dynamo-electric machinery, rests largely upon the researches of the American scientist, Joseph Henry. In 1834–35, only three years after his invention of the electric motor, and a decade following Faraday's discovery that electricity could produce continuous motion, Thomas Davenport, a blacksmith of Brandon, Vt., mounted a toy motor and primary battery on a small vehicle and operated it on a short circular track. This experiment marked the inception of the electric railway, but for two score years many inventors laboured with small result. Among them were Jacobi on the River Neva, and Robert Davidson of Aberdeen, who about 1838 built a five ton locomotive which made several trips on the Edinburgh-Glasgow railway. The use of the rails to conduct current was first shown in an English patent granted to Henry Pinkus in 1844, while French and Austrian patents were granted to Major Bassolo the following year which indicated the use also of a third rail. In 1847, Prof. Moses G. Farmer, one of the earliest experimenters with incandescent lights, operated a small car at Dover, N.H., while three years later one Thomas Hall exhibited in Boston an automatically reversing car mounted on rails. These are the first recorded instances in which the rails were actually used as carriers of the current, as well as the first use of gear reduction from motor and axle. Soon afterwards Prof. Page of the Smithsonian Institution constructed a locomotive which, driven by a battery of 100 Grove elements, was operated on April 29, 1851 on a road near Washington. These early experiments were doomed to commercial failure, because the source of power was a primary battery, but they indicated what was possible with the evolution of the dynamo-electric machine.

Development of the Dynamo.—Beginning with improvements by Wheatstone and Cook in 1845 and by Hjork in 1854, in 1858 an unknown inventor disclosed the vital principle of self-excitation of the field magnets, and three years later came Pacinotti's invention of the continuous-current dynamo, followed shortly by announcement of self-excitation, developed also independently in 1866–67 by Wheatstone, Varley and Ladd in England, Siemens in Germany, and Farmer in the United States. Three years later Gramme combined the two vital features in a single machine, and to him is due the credit of producing the first commercial machine for continuous current operation.

Some time elapsed before the remarkable characteristic of reversibility of function was known, with the natural corollary of the electric transmission of energy by the use of two similar machines connected in the same circuit, one generating and the other reconverting electricity. It is the fundamental of all modern power development of whatever character. It has been claimed that this principle was enunciated by Pacinotti in 1867, but certainly no use of it was made until about 1873, when Gramme and Fontaine demonstrated it at the Vienna Exposition.

The first public demonstration using the dynamo-electric machine was made at the Berlin Exhibition in 1879 by the Siemens firm. The transmission of electric energy for transportation was a

natural sequence, and at this exhibition was installed and operated an equipment comprising a third of a mile of track, a small locomotive and three cars having a capacity of about 20 people. The current was supplied through a central rail, with running rails for a return. The motor was carried longitudinally, motion being transmitted through spur and bevel gears to a central shaft from which connection was made to the wheels. This exhibit was followed by others at Brussels, Düsseldorf and Frankfort, but the first regular line, a short one with one motor car, was installed at Lichterfelde, and opened for traffic in May 1881. At first both rails were used for conducting the current at low potential. The motor was carried on a frame underneath the car between the wheels, the power being transmitted to the axles by steel cables, and a maximum speed of about 30 m. was attained. Some years later the rail distribution was replaced by overhead conductors. The Siemens firm also installed at the 1881 Paris Exposition a tramway about a third of a mile long. The overhead conductors consisted of two slotted tubes, in which slid shoes held in contact by an underrunning wheel on a framework supported by the conductors and connected to the car by flexible cables. The motor was placed between the wheels and the power transmitted by a chain.

EARLY AMERICAN EXPERIMENTS

About this same period various American inventors undertook experimental work. With the possible exception of one George Greene of Kalamazoo, Mich., who repeated some of the early primary battery experiments, apparently the first of these were Stephen D. Field and T. A. Edison. These inventors became involved in a patent interference with each other and with Siemens, all having filed applications within a few months in 1880. Siemens' early testimony was rejected under the existing rules and priority for limited features was awarded to Field, who filed a caveat in 1879, in February of which year he made plans for an electric railway to use current from a stationary generator through a conductor carried in a conduit, with rail return.

In 1880 at Menlo Park, Edison operated a small electric locomotive pulling a trail car. Two of his early lighting dynamos were used, one for generating the current and the other as a motor. The two rails, insulated from each other, were used for current supply through wheel contact, one wheel being insulated from the axle. The power was transmitted to the axle and at first the speed was varied by a friction drum or a belt with a tightener. Two years later, at the instance of Henry Villard, similar experiments were repeated on a larger scale but without material change. The system was impracticable because the use of the two rails as conductors was prohibitive on account of the impossibility of preventing short circuits under commercial conditions. The method of transmitting and controlling power was likewise impracticable. Siemens meanwhile continued work, constructing experimental roads near Meran in the Tyrol and elsewhere.

At a somewhat earlier period F. J. Sprague, a midshipman in the U.S. navy, had constructed in 1881 a series-parallel controlled dynamo and motor of novel design, this method of control having also been independently invented in England by Dr. John Hopkinson the year before. While acting as a juror at the 1882 Crystal Palace Electrical Exhibition Sprague considered the possibility of operating the District Railway electrically, first planning the use of main and working conductors, the latter to be carried between the tracks with automatic means for maintaining tension; but to meet the complication of switches he later conceived the idea of a car moving freely between two contact planes, the terminals of a constant potential generating system, for which in practice would be substituted the rails and switches, with wheel contact, and roof-supported conductors following the centre lines of tracks and switches, with under contact from a compensating device carried on the car over the centre of the trucks. This was the genesis of the present trolley in tramway and main line practice, but was not put into effect until four years later.

In the fall of 1882 Dr. Finney of Pittsburgh proposed operating omnibuses electrically with current from overhead wires carrying a small trolley connected to the vehicle with a flexible cable, while in England Profs. Ayrton and Perry read a paper on automatic railways before the Royal Institution, and Dr. Fleeming Jenkin, the distinguished Scotch scientist, proposed a telepherage system, or automatic overhead railway for carrying merchandise. The development by Faure and Brush of the storage battery was followed by experiments in London and Berlin in 1883 by Reckenzaun. Here the car body was carried by two trucks, each equipped with a motor and worm gear drive. Two sets of brushes were used and speed varied by using the batteries in series or parallel, with resistances to reduce sparking in changing.

The Development Period.—In the United States a Belgian, Charles J. Van Depoele, originally a sculptor and an indefatigable worker, attacked the railway problem, on which he left a permanent impress. His first experiment, using an arc light dynamo as a motor and taking current from a wire laid in a trough, was made at his shop in Chicago in the winter of 1882–83, and in the following autumn the car was exhibited at the Chicago Industrial Exhibition. About this period he tried out an underrunning contact, and in a patent interference with Sprague three years later was successful, because the latter's testimony as to conception prior to reentry in the United States in May 1883 was not available. The English-born Leo Daft in 1883 began work at Greenville, N.J., continuing at Saratoga, where his locomotive, "The Ampere," pulled a full sized car. The motor was mounted on a platform and connected by belts to an intermediate shaft carried between the wheels, from which another set of belts led to pulleys on the driving axles. Current supply was by centre and running rails at low potential. Speed variation was obtained by variation of field resistances, both iron and copper being used. In Great Britain, the first installation was for the Portrush Electric railway in Ireland, in 1883 by Siemens Brothers of London and Hopkinson. The power was generated by a water turbine and current at 250 volts transmitted by a third rail carried on posts along the track, with track return.

Following their experiments in the United States the Field and Edison interests were combined in a corporation, which first operated a small locomotive equipped with a Weston machine at the Chicago Railway Exposition in 1883. The motor was connected by bevel gears to a shaft from which power was transmitted by belts to one axle, and the current was taken from a centre rail with track return. A lever operated clutches on the driving shaft and the speed was varied by resistances. Reversal of movement was effected by two movable brushes, only one of which could be thrown into the circuit at a time. A short experiment was made by Field at Stockbridge and another on the 34th street branch of the New York Elevated, but no commercial installations were made by the company. Field later joined with Eickemeyer in the development of a side-rod driven equipment but this was short-lived.

The use of the conduit for carrying the conductors was undertaken by Bentley and Knight, who in 1884 installed a 2 m. section and two cars on the tracks of the East Cleveland Railway Company, the wooden conduits being laid between the tracks. The motors were carried under the car bodies and power transmitted by cables. This installation was operated during the following winter and abandoned later. At this period J. C. Henry entered the field and installed a small line in Kansas City, using two overhead conductors on each of which travelled a trolley connected to the car by a flexible cable. The motor was mounted on a frame supported on the car axle, with power transmitted through a clutch and a nest of gears. Experiments conducted on another section of the road included use of the rails as a return circuit. The collectors were of different types but the preferred one was a trolley carried by and gripping the sides of the wires.

In the next two years Prof. Short of Denver began experiments on a short track, and the construction with Nesmyth of a section for conduit operation. The series system was used, a constant current being sent through all the motors on the line by automatic sectionalizing of the conductors, the total potential varying according to the number of motors. Speed and direction were varied by shifting the commutator brushes or diverting a part of the current around the motor. The experiments were continued into the following year and repeated at Columbus but failed because of the principle involved.

Daft and Van Depoele meanwhile were continuing work, the former making an installation on the Union Passenger railway of Baltimore, the first in the United States to regularly operate for fares. Here were installed four dummies which pulled regular street cars. Centre and running rails were used for the normal current supply, and at crossings an overhead conductor with under-running contact. Daft's most ambitious project was the equipping of a 2 m. section of track on the Elevated road, on which tests were conducted late in 1885 with the "Benjamin Franklin," operated by a motor mounted on a platform and pivoted at one end, the drive being through grooved friction drums held in close contact. Then followed installations in Los Angeles and elsewhere, using double overhead wires carrying a trolley carriage with flexible connection to the cars.

Van Depoele's work in this period was the equipping of a locomotive, current being taken from an underground conduit, to pull a train at the Toronto Exhibition. In the following year he used an overhead wire and a weighted under-contact arm at the end of the car. His next installations were on the South Bend railway with several cars, and in Minneapolis, where an electric car took the place of a steam locomotive. The next year he equipped a road at Montgomery, Ala., first using a travelling trolley connected to the car by a flexible conductor, but later a non-reversible under-running contact mounted at one end of the car. Other small installations were made in Windsor, Ont., Detroit, Mich., Appleton, Wis., and Scranton, Pa. In these equipments the motor was carried on the platform and connected to the wheels by belts or chains. The cars operated from one end only.

Following motor exhibits at the Philadelphia Electrical Exhibition in 1884, Sprague in the following year essayed a major project, the equipment of the New York elevated system with motors carried on the regular car trucks, beginning actual construction of a test equipment that was transferred to the 34th street branch of the "L" where regular tests began in May 1886. These motors were the parent models of modern equipment. They were centred on the driving axles, connected to them by adjustable single-reduction gears, and the free ends were carried by springs from the transom, now known as the "wheelbarrow suspension." One set of brushes was used for both directions of movement, and the motors were used not only for propulsion but for braking. A shunt field coil was supplemented by a coil in series with the armature at right angles to the normal field, to prevent shifting of the neutral brush point, this being the first "interpole" winding used on railway motors. They were operated at 600 volts, at each end of the car by similar switches, and variation of speed was effected by inverse changes of resistances and field strength. This control provided the means for regeneration, energy being first returned to the line when slowing down from high speed and the motor circuit then closed on itself. Then construction began of a locomotive car of 300 h.p. capacity, all axles to be equipped. Later followed motors for experiments with storage batteries in Philadelphia, New York and Boston in 1886.

In Europe a short road was installed at Bessbrook-Newry under the direction of the Messrs. Hopkinson in 1885, and one at Ryde in 1886, in which year Holroyd Smith equipped the Blackpool road, using a conduit with a complete metallic circuit, the first of this type abroad. The motor was carried under the car between the axles and connected by chain gearing. Fixed brushes with end contact were used for both directions in running.

The Trolley Age.—Reviewing the conditions in 1887, eight years after the Berlin Exhibition by Siemens, there were only nine installations in Europe and ten in the United States, with an aggregate of about 60 m. of track and less than 100 motors and motor cars, characterized by the utmost diversity of practice. The art was in a chaotic state and commercial success on a large scale, with radical improvements in practice, was essential to focus the advantages claimed for electric traction. In the spring of this year three important contracts were made—two, those for the Union Passenger railway of Richmond, Va., and St. Joseph, Mo., by Sprague; and one for the Observatory Hill railway of Allegheny City, Pa., by Bentley-Knight. The latter road was about 4 m. long, one-quarter being of conduit construction and the remainder having a double trolley line on side poles supporting a travelling trolley. There were 34 curves and many heavy grades, the maximum being over 12% and one averaging 6% for nearly a mile. The cars were equipped with two 15 h.p. over-hung motors geared to the axles, and the control was by resistance variation. This line was opened in 1888 and continued in service for some time, but the conduit was abandoned and new equipment installed with an under-running trolley.

The Richmond contract called for completion in 90 days of an installation for a road with 12 m. of track, at that time unlaid and with route undetermined, of equipment for a complete steam and electric central-station plant and 80 motors on 40 cars, with all the appurtenances necessary for operation. This was nearly as many motors as were in use on all existing installations. Thirty cars were to be operated at one time and many heavy grades and curves negotiated. Finally, the payment was to be $120,000 "if satisfactory." Experimental operation began in the fall of 1887 and regular service in Feb. 1888. The difficulties met were numerous, but after many vicissitudes which taxed the technical and financial resources of the company, success was achieved, and the Richmond road is now recognized as the first of the modern systems in which a large railway was equipped and operated under service conditions by electricity, and as the pioneer of commercial electric traction.

Its features included distribution by an overhead line over the centre of the track, reinforced by a main conductor in turn supplied at central points from a constant potential plant operated at 450 volts, and with reinforced track return. Current was taken from the overhead line, at first by fixed upward pressure contacts and later by a wheel carried on a pole supported over the centre of the car and having free up and down and reversible movement. Series-wound motors, one to each axle, were centred on and geared to them on the wheelbarrow suspension method, at first by single adjustable and then by double reduction gears. All the weight was available for traction and the car could be operated in either direction from either end of the platform. Control was at first by variation of the field coils from series to multiple relation and series-parallel grouping of armatures by a separate switch. Motors were run in both directions with fixed brushes, at first laminated ones placed at an angle, then solid metallic ones with radial bearing and finally carbon ones as proposed by Van Depoele.

Prior to this time the cable system had been adopted on several roads and was under consideration for the West End road of Boston, but was abandoned by its president, Henry M. Whitney, in favour of Sprague equipment. Soon afterwards the cable road in Minneapolis was abandoned. Meanwhile the Van Depoele interests had been absorbed by the Thomson-Houston Electric Company and there followed a period of extraordinary activity in the United States, in which this company and the Sprague Electric Railway and Motor Company were the principal competitors. It resulted in contracts for over 200 railways within two years. There followed continuous improvement and increase in the size of apparatus. Form-wound armatures, proposed by Eickemeyer, replaced irregular windings, and metallic brushes gave way to carbon, this single change initiated by Van Depoele being of prime importance. Cast and wrought iron yielded to steel, two-pole motors to four-pole, double reduction gears to single, and open motors to closed, protected by their own castings. In 1892 the Reckenzaun-Condict single movement series-parallel and resistance control was adopted and the Thomson magnet blow-out successfully applied to controllers by Potter.

The rapid spread of electric railway in the United States resulted in installations in Europe at Florence-Fiesole, Halle and elsewhere, but it was not until some time later that there was any general adoption of the electric railway. Meanwhile the Sprague Company was absorbed in 1890 by the Edison General Electric Company, which later combined with the Thomson-Houston Company and others in the General Electric Company, and the Westinghouse Company also entered the field.

Effect on Telephone Systems.—No sooner had the Richmond road started than there was emphasized a series of disturbances on the telephone lines, it being the general practice to install tele-

phones with earth return circuits. The service had become unsatisfactory because of the multiplicity of electric installations of various kinds, with consequent ground leakages and troubles from induction. The first attempt to meet this trouble was to replace the ground connection by a metallic return, which obviated most leakage troubles but did not get rid of induction. Numerous lawsuits followed, the telephone companies attempting to force the railways to use double overhead circuits, but the trolley contentions were in the main successful and individual balanced metallic circuits, vital to successful operation and without which the long distance telephone is impracticable, were finally adopted.

Heavy Electric Traction.—Despite the success of the trolley there was little immediate effort to extend electric operation to other types of railroad service, and for the next six years the record is that of an industrial development, the replacement of horse and cable power on existing lines and the creation of new ones. However, in Nov. 1890, the South London line, originally designed for cable, was opened, using Siemens' electric gearless locomotives, and in Feb. 1892 Sprague offered to install on the New York elevated road two test trains, one to be operated by a locomotive car and the other with motors distributed under the cars, and to make a speed of 40 m. per hour. A year later the Liverpool overhead railway was put in operation, with two-car trains, each with one motor but both operated by direct control. In the spring of the same year the Intramural railway was constructed at the Chicago World's Fair with equipment supplied by the General Electric Company, and two years later the Metropolitan West Side elevated road in the same city was equipped on the same general plan, both installations using a motor car to pull trail cars. In May 1896, the Nantasket Beach road, a branch of the New York and New Haven railway, was put in operation; in September the Lake street elevated of Chicago, and shortly afterwards electric service began on the Brooklyn bridge. There were few attempts, however, to replace steam on main line roads, and only occasionally were electric locomotives used for special reasons. Among the earlier ones built were one of 1,000 h.p. in 1892–93, designed by Sprague, Duncan and Hutchinson for Henry Villard for experimental operation on lines out of Chicago, and the still larger locomotive built by the General Electric Company, which began hauling trains in the Baltimore and Ohio tunnel in 1895.

For a long time the conduit system, after its abandonment in Allegheny City and Boston, remained undeveloped and installations were with the overhead trolley, using 500 volt direct current series motors. The first important installation in the United States using a metal conduit in which the two conductors are supported and current collected by a plough carried by the car and projecting through the slot was made in Washington under the direction of Connett. The success of this installation and of tests carried out on the Lenox avenue line in New York led to the adoption of this type in many cities in the United States and Europe where the capital expenditure seemed to warrant it.

The development of interurban railways was aided by the inventions in polyphase alternating current transmission by Tesla, Farraris and Stanley, and in rotary transformers by Bradley and others. The first proposal to use these in electric railways seems to have been made in 1896 by B. J. Arnold, in plans for a road near Chicago. This road was not built but the plans were utilized for a line two years later, which was the forerunner of the standard practice of to-day.

The Multiple-Unit System.—Although the limitation of distance had been thus practically eliminated by the adoption of alternating current for the initial transmission of electric energy to sub-stations from which it could be delivered to the working conductor, whether overhead with running or sliding contact or to protected third rails with top or bottom contacts, there remained the limitations of operating motor potential and unit capacity of equipment. The former led to the gradual raising of direct-current operating potential from 500 to 3,000 volts, with interpole motors, in the face of much criticism, and the use of alternating currents on overhead lines up to 11,000 volts, and the latter to a new system of control known as the "Multiple-Unit," invented by Sprague in 1895 and first installed on 120 cars of the South Side elevated road in Chicago in 1897. This is a system of electrical control of controllers, by means of which any number of individually equipped cars or locomotives, with or without unequipped units, may be assembled in any desired manner, end-relation or sequence, and operated from any one of a number of master controllers through a secondary train line extending throughout the train, with provision for automatic equalization of duty on the different equipments. This development has made possible great aggregations of power under remote control, and the system has been universally adopted on all electrical elevated and subway rapid transit lines, with great resulting increase of capacity and speed of operation, and on all suburban trains and locomotives operated on electrified main lines where two or more units are under a single control.

Future of Electric Traction.—The advantages of electric operation as compared with horse or cable operation are so manifest that the latter has been practically displaced, and this form of electric utility has grown until in the United States alone it represents a capitalization of $6,000,000,000 and an employment of 350,000 people. But the advent of the gasolene engine for private and public vehicles has militated against trolley as well as main line railroad operation, so that in many cases electric roads, with their restricted route, high capital investment and reduced patronage have been abandoned, while the remainder have been obliged to improve equipment and service. Despite these handicaps the trolley, as a system, will continue. Where traffic is concentrated, as on rapid transit lines with exclusive rights of way, no other form of present known motive power can approach electric operation in capacity, efficiency and economy.

The electrification of the standard main line railroads, although slow in beginning, is now making definite progress and will proceed at an accelerated pace. At first, on account of the high capital costs installations were confined to special conditions, as the operation of city terminals and tunnels. For a general solution the use of high electrical pressure is vital, and before the increased possibilities of the direct current motor were demonstrated this need led to attempts to use both polyphase and single phase alternating currents without intermediate moving wayside apparatus. One of the earliest undertakings of this kind was the high speed test on the Zossen Military line in 1903, where a car was operated at 126 m. per hour, current being supplied on the polyphase system from three overhead wires through sliding contacts at 14,000 volts pressure. The Valentina line, equipped by Ganz, also used the polyphase system, but with the rails as one conductor and at a lower pressure of 6,000 volts. In the United States a like equipment was installed on the Great Northern railway, but this has been abandoned. The multiplicity of conductors militates against this system, and where used directly alternating current will be supplied through a single overhead trolley line supported by a catenary.

On the other hand, certain advantages inherent to the direct current motor, the raising of its operating potential to 3,000 volts, the development of the mercury rectifier and the automatic substation, the growing density of traffic and the expanding general uses of electricity from central generating stations, inter-connected but maintaining the advantages of primary transmission by polyphase alternating currents at high pressures, have strongly entrenched the direct current motor as a favoured form of locomotive equipment. One difficulty experienced has been decision as to type of locomotive. The early ones either carried the armatures on the axles or geared the motor to them, as in trolley car practice. Then appeared the Bachelder direct bi-polar type, in which the armatures are carried on the axles, while the field magnets, with flattened pole pieces and tandem magnetic flux, form part of the spring-supported super-structure. The raising of the centre of gravity to reduce lateral pressures on the rails has been obtained by gearing motors to jack shafts from which drive rods extend to the side rods, while in other forms direct connection of motor to side rods is made through automatic adjusting couplings, so as to allow support of the motor above the springs. Experience will determine which forms are best adapted for special and general service, and the electric locomotive will

inevitably achieve supremacy because of the possible concentration of power, ability to maintain speeds on heavy grades, capacity of continuous duty, and the advantages of regenerative braking, low cost of upkeep and simplicity of operation.

Among conspicuous installations in the United States are the New York Central terminal, operated with Wilgus and Sprague under-contact protected third rail at 600 volts, the New York, New Haven and Hartford railroad with 11,000 single phase trolley and motors, the Butte and Montana and the 437 m. section of the Chicago, Milwaukee and St. Paul railroad, operated with direct current motors at 2,400 and 3,000 volts respectively, the Virginian, with single phase trolley and split-phase polyphase motors, and the extensive installations projected for the Pennsylvania, Lackawanna and New York Central railroads, and many important railroads in France, Italy, Switzerland and elsewhere. In Switzerland, electrification, aided by abundant water-power, had by the end of 1928, according to the report made by technical director Dr. E. Huber to the Zurich Natural History Society, reached 58% of route, 67% of track and 85% of trailing-ton miles —an augury of the passing of the steam locomotive. (F. J. Sp.)

ELECTRIC WAVES. The enormous development in the use of electrical waves for wireless telegraphy and other purposes has led to such a multitude of investigations on their properties and the methods of producing and detecting them that the subject has become far too large to be dealt with in one article. A detailed account of the present position of various branches of the subject will be found in the articles WIRELESS, THEORY OF; WIRELESS, PRACTICE OF; THERMIONIC VALVES; ELECTROMAGNETIC SPECTRUM. This article will deal with the history of the initiation of the subject and the first stages of its development.

Clark-Maxwell.—It is to Clark-Maxwell that we owe not only the origination of the idea that electrical and magnetic effects are propagated by waves, but also the establishment of equations giving a mathematical theory by which these effects can be calculated. The equations known as Maxwell's equations are, if we accept the view that the constitution of matter is fundamentally electrical, the key to the solution of many of the most fundamental problems in physics. Maxwell's discovery was inspired by Faraday's view that the forces between electrified bodies was not due to direct action at a distance between the electric charges on these bodies, but to the presence in the region occupied by these bodies of lines of force, these lines started from bodies charged with electricity of one sign and ended on bodies charged with electricity of the opposite sign; these lines of force were supposed to be in a state of tension, and thus were striving to shorten while at the same time they repelled laterally the adjacent lines of force. These tensions and repulsions produced in Faraday's view the forces which electrified bodies exert on each other. Maxwell's first paper was "On Faraday's Lines of Electric Force" (*Proc. Cambridge Philosophical Society*, x. part i., 1855). In this he puts Faraday's conception into a form suitable for mathematical treatment by the introduction of the idea of tubes of force, a tube of force being the tubular service formed by the lines of force which pass through a small closed curve drawn in the electric field. He shows that the electric force at any point along this tube is inversely proportional to the cross section of the tube at the point, so that the tubes are thinner when the force is large than when it is small, and the variations in the sizes of the tube will indicate the variation in the electric force. These tubes start from positively electrified bodies and end on negatively electrified ones. The charge enclosed by the tube on the surface from which it starts is equal to the charge it encloses on the surface where it ends, if the size of the tube is chosen so that this charge is unity. Thus a charge of electricity e will be the origin or terminus of e tubes of force. In the *Philosophical Magazine*, March, April, May 1861, he works out a theory of magnetic lines of force, supposing that a tube of magnetic force is a vortex whose axis of rotation coincides with the direction of the force, he shows that these vortexes would give rise to forces analogous to those observed in the magnetic field. Inasmuch as contiguous positions of neighbouring vortexes must be moving in opposite directions he supposes that the vortexes are separated by particles which act like the idle wheels in a train of mechanism, so that each vortex has a tendency to make a neighbouring vortex rotate in the same direction as itself. The motion of these particles constituted in Maxwell's view the electric current. Though Maxwell in his later papers did not make much reference to this theory, it seems to have been the consideration of this hypothetical mechanism which suggested the conception which is the very keystone of his theory in the final form given in the paper "A Dynamical Theory of the Electromagnetic Field" (*Phil. Trans.*, clv. 1864). This conception was that magnetic forces could be produced not only by the ordinary convective currents flowing through wires and electrolytes which had previously been supposed to be the sole source of magnetic force, but by another type of current to which he gave the name of displacement currents, and which can occur in insulators as well as conductors. The displacement current exists when the electric force is changing and the components of the intensity of this current, *i.e.*, the current per unit area parallel to the axes x, y, z are

$$\frac{K}{4\pi}\frac{dX}{dt},\quad \frac{K}{4\pi}\frac{dY}{dt},\quad \frac{K}{4\pi}\frac{dZ}{dt}$$

where X, Y, Z, are the components of the electric force and K the specific induction capacity of the medium.

Different Theories.—The difference between Maxwell's theory and the earlier ones is well illustrated by the consideration of the charging up of a condenser. Suppose the condenser consists of two parallel metal plates A and B and that it is charged by connecting A and B by wires with the terminals of a battery, if Q, −Q are the charges at a time t on the plates, then there is a convective current i along the wires equal to dQ/dt, this on the old view would be the only current that would have to be taken into account when calculating the magnetic forces; there would be no currents in the dielectric between the plates and the magnetic forces in that region would be derivable from a potential. On Maxwell's view there is a displacement current between the plates equal to $\frac{K}{4\pi}\frac{dX}{dt}$ per unit area, where X is the electric force between the plates and K the specific inductive capacity of the dielectric separating them. The density of the electricity on a plate is equal to Q/A where A is the area of a plate, hence by Coulomb's law

$$KX = 4\pi Q/A$$

so that

$$\frac{K}{4\pi}\frac{dX}{dt} = \frac{1}{A}\cdot\frac{dQ}{dt} = \frac{i}{A}$$

where i is the current through the wires, this is the expression for the displacement current per unit area, the total current across the area A is equal to Ai/A or i. Thus the displacement current through the dielectric is the same as the current through the wire, so that the Maxwellian currents form a closed circuit; this can easily be seen to be true generally, so that on Maxwell's theory all current circuits are closed. The displacement as well as the convective currents admit of simple representation in terms of the motion of tubes of electric force (J. J. Thomson, *Elements of Electricity and Magnetism*, chap. xiii.). The wave propagation of electric and magnetic force is an immediate consequence of Maxwell's generalization of the idea of an electric current. For let u, v, w be the components of the effective current, (X, Y, Z) (α, β, γ) the components of the electric and magnetic force respectively, K the specific inductive capacity of the medium, μ its magnetic permeability. The equations which express Ampères law that the work done in taking a magnet pole round a closed circuit is equal to 4 times the current passing through the circuit arc.

$$\left.\begin{aligned} 4\pi u &= \frac{d\gamma}{dy} - \frac{d\beta}{dz}, \\ 4\pi v &= \frac{d\alpha}{dz} - \frac{d\gamma}{dx}, \\ 4\pi w &= \frac{d\beta}{dx} - \frac{d\alpha}{dy} \end{aligned}\right\} \qquad A$$

while those which express Faraday's law that the electromotive force round a closed circuit is equal to the rate of diminution of the magnetic induction through the circuit are

$$\left.\begin{aligned}-\mu\frac{d\alpha}{dt}&=\frac{dZ}{dy}-\frac{dY}{dz}\\ -\mu\frac{d\beta}{dt}&=\frac{dX}{dz}-\frac{dZ}{dx}\\ -\mu\frac{d\gamma}{dt}&=\frac{dY}{dx}-\frac{dX}{dy}.\end{aligned}\right\}\quad B$$

Take now the case of a dielectric in which there are no convective currents, then $u=\frac{K}{4\pi}\frac{dX}{dt}$, hence differentiating (1) of A with respect to t we have

$$K\frac{d^2X}{dt^2}=\frac{d}{dy}\frac{d\gamma}{dt}-\frac{d}{dz}\frac{d\beta}{dt}$$

substituting the values of $\frac{dy}{db}$ and $\frac{d\beta}{dt}$ from β, we get, since in the dielectric

$$\frac{dX}{dx}+\frac{dY}{dy}+\frac{dZ}{dz}=0$$

$$\mu K\frac{d^2X}{dt^2}=\frac{d^2X}{dx^2}+\frac{d^2X}{dy^2}+\frac{d^2X}{dz^2}$$

with similar equations for Y, Z, α, β, γ. These equations are of the type of the wave equation

$$\frac{1}{V^2}\frac{d^2\phi}{dt^2}=\frac{d^2\phi}{dx^2}+\frac{d^2\phi}{dy^2}+\frac{d^2\phi}{dz^2}$$

and represent a disturbance propagated as a wave with the velocity V, in the electrical case is given by $V=1/\sqrt{\mu\kappa}$.

Thus we see that on Maxwell's theory the components of the electric and magnetic force in a dielectric satisfy the wave equation, so that electric and magnetic forces travel as waves through the dielectric, the velocity of propagation being $1/\sqrt{\mu\kappa}$. Now μ and κ can be measured by purely electrical methods, the value of $1/\sqrt{\mu\kappa}$ for air being the ratio of the electrostatic to the electromagnetic unit of electricity which has been found by experiment to be very nearly 3×10^{10} ampere, and thus equal to the velocity of light. Thus it follows from Maxwell's theory that electric and magnetic disturbances travel through dielectrics with the velocity of light.

Let us consider the distribution of electric force in a plane electromagnetic wave. If X, Y, Z are the components of the electric force, l, m, n the direction cosines of the normal to the wave front and λ the wave length we may put

$$X,\ Y,\ Z,\ =(X_0,\ Y_0,\ Z_0)\cos\frac{2\pi}{\lambda}(lx+my+nz-VE)$$

since $\qquad \frac{dX}{dx}+\frac{dY}{dy}+\frac{dZ}{dz}=0$

we have $\qquad lX_0+mY_0+nZ_0=0$

so that $\qquad lX+mY+nZ=0$

which expresses the fact that the electric force is perpendicular to the direction of propagation of the waves. From equations B we find.

$$\alpha=KV(nY-mZ)$$
$$\beta=KV(lZ-nX)$$
$$\gamma=KV(mX-lY)$$

Thus $l\alpha+m\beta+n\gamma=0$ and $X\alpha+Y\beta+Z\gamma=0$, thus the magnetic force is at right angles to the direction of propagators of the wave and also to the electric force. We see too that

$$\sqrt{(\alpha^2+\beta^2+\gamma^2)}=KV\sqrt{(X^2+Y^2+Z^2)}$$

so that the magnetic force bears a constant ratio to the electric. Hence in a plane electromagnetic wave the electric and magnetic forces are in the wave front, and at right angles and in constant proportion to each other.

If the medium through which the waves are travelling is a conductor of electricity there will be convective as well as displacement currents, hence if p, q, v are the convective currents

$$u=\frac{K}{4\pi}\frac{dX}{dt}+p;\quad v=\frac{K}{4\pi}\frac{dY}{dt}+q,\quad w=\frac{K}{4\pi}\frac{dZ}{dt}+\nu$$

if the convective currents obey Ohms law, $p=X/\sigma$, if σ is the specific electrical resistance of the material hence

$$u=\frac{K}{4\pi}\frac{dX}{dt}+\frac{X}{\sigma}$$

with corresponding expressions for v, and w, using these expressions in equation A, we find

$$\mu K\frac{d^2X}{dt^2}+\frac{4\pi\mu}{\sigma}\frac{dX}{dt}=\frac{d^2X}{dx^2}+\frac{d^2X}{dy^2}+\frac{d^2X}{dz^2}.$$

This equation represents waves spreading through an absorbing medium the amplitude of the disturbance diminishes exponentially with the distance from the source and the phase velocity of the waves diminishes with their frequency.

If the frequency of the vibrations is p, $\mu K\frac{d^2X}{dt^2}=-\mu Kp^2X$ and $\frac{4\pi\mu}{\sigma}\frac{dX}{dt}=-\frac{4\pi\mu\iota}{\sigma}pX$, hence if p is large compared with $4\pi/K\sigma$, the second term on the left hand side of above equation is small compared with the first and may be neglected and the equation approximates to the wave equation, if on the other hand p is small compared with $4\pi/K\sigma$ the first term is small compared with the second and the equation approximates to that which expresses the conduction of heat.

Passage of Electrical Waves Through an Ionized Gas.—A case of great importance in the theory of the propagation of electrical waves through the atmosphere is when the conductivity of the medium is due to the presence of gaseous ions and the pressure of the gas is so low that the motion of the ions is not interfered with by collisions with the molecules of the gas. In this case p, q, r the components of the convective current are given by the equations

$$p=\Sigma e\dot{\xi},\quad q=\Sigma e\dot{\eta},\quad r=\Sigma e\dot{\zeta}$$

where $\dot{\xi}$, $\dot{\eta}$, $\dot{\zeta}$ are the components of the velocity of an ion, e discharge and the summation is to be extended to all the ions in unit volume. Thus $\frac{dp}{dt}=\Sigma e\ddot{\xi}$

and since the motion of the ions is free

$$m\ddot{\xi}=Xe,$$

where m is the mass of an ion.

Thus if u is the total current

$$\frac{du}{dt}=\frac{K}{4\pi}\frac{d^2X}{dt^2}+\Sigma re\ddot{\xi}$$
$$=\frac{K}{4\pi}\cdot\frac{d^2X}{dt^2}+\frac{\Sigma e^2}{m}\cdot X$$

if there are n negative and n positive ions per unit volume

$$\Sigma\frac{e^2}{m}=Ne^2\left(\frac{1}{m_1}+\frac{r}{m_2}\right)X=p_0^2,$$

where m_1, m_2 are the masses of the negative and positive ions respectively, using this value of du/dt in equations (A) we get

$$\mu K\frac{d^2X}{dt^2}+4\pi\mu\cdot p_0^2X=\frac{d^2X}{dx^2}+\frac{d^2X}{dy^2}+\frac{d^2X}{dz^2}-\frac{d}{dx}\left(\frac{dX}{dx}+\frac{dY}{dy}+\frac{dZ}{dz}\right)$$

for the electric forces and

$$\mu K\frac{d^2K}{dt^2}+4\pi\mu p_0^2\alpha=\frac{d^2\alpha}{dx^2}+\frac{d^2\alpha}{dy^2}+\frac{d^2\alpha}{dz^2}$$

for the magnetic. This equation differs from that for a non-conducting dielectric by the presence of the term $4\pi\mu p_0^2\alpha$ on the left hand side, and this produces effects which differentiate sharply the behaviour of waves in a non-conducting and in an ionized medium.

These differences are (1) waves of any frequency can travel through the insulating medium while through the ionized one it is only waves whose frequency is greater than $p_0\sqrt{\frac{4\pi}{K}}$ which are able to do so; (2) the phase velocity of the waves in the insulating medium is independent of the wave length and equal to c the velocity of light; in the ionized medium, if V is the phase velocity and λ the wave length $V^2=c^2+\frac{p_0^2\lambda^2}{K}$ thus the phase velocity is always greater than the velocity of light and is infinite for infinitely long waves. (3) In the insulating medium the energy travels out with the velocity c, in the ionized medium it travels with the velocity $V-\lambda\frac{dV}{d\lambda}=c^2/V$, since V is always greater than c, the velocity of the energy in the ionized medium is less than in the insulating one.

The velocity of the waves in the ionized medium depends upon the value of p_0^2 a quantity which is proportional to the number of ions per cubic centimetre in the medium. Thus if the number of ions in the upper regions of the atmosphere varies with the height above the surface of the earth the waves in these regions will be passing through a medium in which the refractive index varies from place to place, this, as in the analogous optical case of the mirage, will lead to a bending of the waves so that instead of continually travelling away from the earth they may be bent round so as to return to it. There are good reasons for believing that in the upper regions of the atmosphere there is a layer of ionized gas, known as the Heaviside side, and that this plays a most important part in long distance wireless. (*See* WIRELESS, THEORY OF.)

Hertz's Experiments.—Though Maxwell's theory was published in 1864, it was not until 1887, seven years after the death of Maxwell that any direct experimental proof of its validity was obtained. On Maxwell's theory electrical waves ought to radiate from any system in which electrical oscillation is produced. Lord Kelvin, in 1853, proved from electromagnetic theory that the discharge of a condenser is oscillatory, a result which Feddersen (*Pogg. Ann.*, 103 p. 69) verified by a series of beautiful experiments. The oscillatory character of the discharge of a condenser had been inferred by Henry as long ago as 1842 from his experiments on the magnetization produced in needles by the discharge of a condenser. Thus, if Maxwell's theory is true, electric waves must pass through the dielectric surrounding a condenser in the act of discharging, but it was not until 1887 that the existence of such waves was proved by direct experiment. This great step was made by Hertz (*Wied. Ann.* 34, pp. 155, 551, 609; *Ausbreitung der elektrischen Kraft*, Leipzig, 1892), whose experiments on this subject form one of the greatest contributions ever made to experimental physics. The difficulty which had stood in the way of the observations of these waves was the absence of any method of detecting electrical and magnetic forces, reversed some millions of times per second, and only lasting for an exceedingly short time. This was removed by Hertz, who showed that such forces would produce small sparks between pieces of metal very nearly in contact, and that these sparks were sufficiently regular to be used to detect electric waves and to investigate their properties. Other and more delicate methods have subsequently been discovered, but the results obtained by Hertz with his detector were of such signal importance, that we shall begin our account of experiments on these waves by a description of some of Hertz's more fundamental experiments.

To produce the waves Hertz used two forms of vibrator. The first is represented in fig. 1. A and B are two zinc plates about 40 cm. square; to these brass rods, C, D, each about 30 cm. long, are soldered, terminating in brass balls E and F. To get good results it is necessary that these balls should be very brightly polished, and as they get roughened by the sparks which pass between them it is necessary to re-polish them at short intervals; they should be shaded from light and from sparks, or other source of ultra-violet light. In order to excite the waves, C and D are connected to the two poles of an induction coil; sparks cross the air-gap which becomes a conductor, and the charges on the plates oscillate backwards and forwards like the charges on the coatings of a Leyden jar when it is short-circuited. The object of polishing the balls and screening off light is to get a sudden and sharp discharge; if the balls are rough there will be sharp points from which the charge will gradually leak, and the discharge will not be abrupt enough to start electrical vibrations, as these have an exceedingly short period. From the open form of this vibrator we should expect the radiation to be very large and the rate of decay of the amplitude very rapid. Bjerknes (*Wied. Ann.* 44, p. 74) found that the amplitude fell to $1/e$ of the original value, after a time 4T where T was the period of the electrical vibrations. Thus after a few vibrations the amplitude becomes inappreciable. To detect the waves produced by this vibrator Hertz used a piece of copper wire bent into a circle, the ends being furnished with two balls, or a ball and a point connected by a screw, so that the distance between them admitted of very fine adjustment. The radius of the circle for use with the vibrator just described was 35 cm., and was so chosen that the free period of the detector might be the same as that of the vibrator, and the effects in it increased by resonance. It is evident, however, that with a primary system as greatly damped as the vibrator used by Hertz, we could not expect very marked resonance effects, and as a matter of fact the accurate timing of vibrator and detector in this case is not very important. With electrical vibrators which can maintain a large number of vibrations, resonance effects are very striking, as is beautifully shown by the following experiment due to Lodge (*Nature*, 41, p. 368), whose researches have greatly advanced our knowledge of electric waves. A and C (fig. 2) are two Leyden jars, whose inner and outer coatings are connected by wires, B and D, bent so as to include a considerable area. There is an air-break in the circuit connecting the inside and outside of one of the jars, A, and electrical oscillations are started in A by joining the inside and outside with the terminals of a coil or electrical machine. The circuit in the jar C is provided with a sliding piece, F, by means of which the self-induction of the discharging circuit, and, therefore, the time of an electrical oscillation of the jar, can be adjusted. The inside and outside of this jar are put almost, but not quite, into electrical contact by means of a piece of tin-foil, E, bent over the lip of the jar. The jars are placed face to face so that the circuits B and D are parallel to each other, and approximately at right angles to the line joining their centres. When the electrical machine is in action sparks pass across the air-break in the circuit in A, and by moving the slider F it is possible to find one position for it in which sparks pass from the inside to the outside of C across the tin-foil, while when the slider is moved a short distance on either side of this position the sparks cease.

Hertz found that when he held his detector in the neighbourhood of the vibrator minute sparks passed between the balls. These sparks were not stopped when a large plate of non-conducting substance, such as the wall of a room, was interposed between the vibrator and detector, but a large plate of very thin metal stopped them completely.

To illustrate the analogy between electric waves and waves of light Hertz found another form of apparatus more convenient. The vibrator consisted of two equal brass cylinders, 12 cm. long and 3 cm. in diameter, placed with their axes coincident, and in the focal line of a large zinc parabolic mirror about 2 metres high, with a focal length of 12·5 cm. The ends of the cylinders nearest each other, between which the sparks passed, were carefully polished. The detector, which was placed in the focal line of an equal parabolic mirror, consisted of two lengths of wire, each having a straight piece about 50 cm. long and a curved piece about 15 cm. long bent round at right angles so as to pass through the back of the mirror. The ends which came through the mirror were connected with a spark micrometer, the sparks being observed from behind the mirror. The mirrors are shown in fig. 3.

Reflection and Refraction.—To show the reflection of the waves Hertz placed the mirrors side by side, so that their openings looked in the same direction, and their axes converged at a

point about 3 metres from the mirrors. No sparks were then observed in the detector when the vibrator was in action. When, however, a large zinc plate about 2 metres square was placed at right angles to the line bisecting the angle between the axes of the mirrors sparks became visible, but disappeared again when the metal plate was twisted through an angle of about 15° to either side. This experiment showed that electric waves are reflected, and that, approximately at any rate, the angle of incidence is equal to the angle of reflection. To show refraction Hertz used a large prism made of hard pitch, about 1·5 metres high, with a slant side of 1·2 metres and an angle of 30°. When the waves from the vibrator passed through this the sparks in the detector were not excited when the axes of the two mirrors were parallel, but appeared when the axis of the mirror containing the detector made a certain angle with the axis of that containing the vibrator. When the system was adjusted for minimum deviation the sparks were most vigorous when the angle between the axes of the mirrors was 22°. This corresponds to an index of refraction of 1·69.

Analogy to a Plate of Tourmaline.—If a screen be made by winding wire round a large rectangular framework, so that the turns of the wire are parallel to one pair of sides of the frame, and if this screen be interposed between the parabolic mirrors when placed so as to face each other, there will be no sparks in the detector when the turns of the wire are parallel to the focal lines of the mirror; but if the frame is turned through a right angle so that the wires are perpendicular to the focal lines of the mirror the sparks will recommence. If the framework is substituted for the metal plate in the experiment on the reflection of electric waves, sparks will appear in the detector when the wires are parallel to the focal lines of the mirrors, and will disappear when the wires are at right angles to these lines. Thus the framework reflects but does not transmit the waves when the electric force in them is parallel to the wires, while it transmits but does not reflect waves in which the electric force is at right angles to the wires. The wire framework behaves towards the electric waves exactly as a plate of tourmaline does to waves of light. Du Bois and Rubens (*Wied, Ann.* 49, p. 593), by using a framework wound with very fine wire placed very close together, have succeeded in polarizing waves of radiant heat, whose wave length, although longer than that of ordinary light, is very small compared with that of electric waves.

Angle of Polarization.—When light polarized at right angles to the plane of incidence falls on a refracting substance at an angle $\tan^{-1}\mu$ where μ is the refractive index of the substance, all the light is refracted and none reflected; whereas when light is polarized in the plane of incidence, some of the light is always reflected whatever the angle of incidence. Trouton (*Nature*, 39, p. 391) showed that similar effects take place with electric waves. From a paraffin wall 3ft. thick, reflection always took place when the electric force in the incident wave was at right angles to the plane of incidence, whereas at a certain angle of incidence there was no reflection when the vibrator was turned, so that the electric force was in the plane of incidence. This shows that on the electromagnetic theory of light the electric force is at right angles to the plane of polarization.

Stationary Electrical Vibrations.—Hertz (*Wied. Ann.* 34, p. 609) made his experiments on these in a large room about 15 metres long. The vibrator, which was of the type first described, was placed at one end of the room, its plates being parallel to the wall, at the other end a piece of sheet zinc about 4 metres by 2 metres was placed vertically against the wall. The detector—the circular ring previously described—was held so that its plane was parallel to the metal plates of the vibrator, its centre on the line at right angles to the metal plate bisecting at right angles the spark gap of the vibrator, and with the spark gap of the detector parallel to that of the vibrator. The following effects were observed when the detector was moved about. When it was close up to the zinc plate there were no sparks, but they began to pass feebly as soon as it was moved forward a little way from the plate, and increased rapidly in brightness until it was about 1·8 metres from the plate, when they attained their maximum. When its distance was still further increased they diminished in brightness, and vanished again at a distance of about 4 metres from the plate. When the distance was still further increased they reappeared, attained another maximum, and so on. They thus exhibited a remarkable periodicity similar to that which occurs when stationary vibrations are produced by the interference of direct waves with those reflected from a surface placed at right angles to the direction of propagation. Similar periodic alterations in the spark were observed by Hertz when the waves, instead of passing freely through the air and being reflected by a metal plate at the end of the room, were led along wires, as in the arrangement shown in fig. 4. L and K are metal plates placed parallel to the plates of the vibrator, long parallel wires being attached to act as guides to the waves which were reflected from the isolated end. (Hertz used only one plate and one wire, but the double set of plates and wires introduced by Sarasin and De la Rive make the results more definite.) In this case the detector is best placed so that its plane is at right angles to the wires, while the air space is parallel to the plane containing the wires. The sparks instead of vanishing when the detector is at the far end of the wire are a maximum in this position, but wax and wane periodically as the detector is moved along the wires. The most obvious interpretation of these experiments was the one given by Hertz—that there was interference between the direct waves given out by the vibrator and those reflected either from the plate or from the ends of the wire, this interference giving rise to stationary waves. The places where the electric force was a maximum were the places where the sparks were brightest, and the places where the electric force was zero were the places where the sparks vanished. On this explanation the distance between two consecutive places where the sparks vanished would be half the wave length of the waves given out by the vibrator.

Some very interesting experiments made by Sarasin and De la Rive (*Comptes rendus*, 115, p. 489) showed that this explanation could not be the true one, since by using detectors of different sizes they found that the distance between two consecutive places where the sparks vanished depended mainly upon the size of the detector, and very little upon that of the vibrator. With small detectors they found the distance small, with large detectors, large; in fact it is directly proportional to the diameter of the detector. We can see that this result is a consequence of the large damping of the oscillations of the vibrator and the very small damping of those of the detector. Bjerknes showed that the time taken for the amplitude of the vibrations of the vibrator to sink to $1/e$ of their original value was only 4T, while for the detector it was 500T′, when T and T′ are respectively the times of vibration of the vibrator and the detector. The rapid decay of the oscillations of the vibrator will stifle the interference between the direct and the reflected wave, as the amplitude of the direct wave will, since it is emitted later, be much smaller than that of the reflected one, and not able to annul its effects completely; while the well-maintained vibrations of the detector will interfere and produce the effects observed by Sarasin and De la Rive. To see this let us consider the extreme case in which the oscillations of the vibrator are absolutely dead-beat. Here an impulse, starting from the vibrator on its way to the reflector, strikes against the detector and sets it in vibration; it then travels up to the plate and is reflected, the electric force in the impulse being reversed by reflection. After reflection the impulse again strikes the detector, which is still vibrating from the effects of the first impact; if the phase of this vibration is such that the reflected impulse tends to produce a current round the detector in the same direction as that which is circulating from the effects of the first impact, the sparks will be increased, but if the reflected impulse tends to produce a current in the opposite direction the sparks will be diminished. Since the electric force is reversed by reflection, the greatest increase in the sparks will take place when the impulse finds, on its return, the detector in the opposite phase to that in which it left it; that is, if the time which has elapsed between the departure and return of the impulse is equal to an odd multiple of half the time of vibration of the detector. If d is the distance of the detector from the reflector when the sparks

are brightest, and V the velocity of propagation of electromagnetic disturbance, then $2d/V=(2n+1)(T'/2)$; where n is an integer and T′ the time of vibration of the detector, the distance between two spark maxima will be VT′/2, and the places where the sparks are a minimum will be midway between the maxima. Sarasin and De la Rive found that when the same detector was used the distance between two spark maxima was the same with the waves through air reflected from a metal plate and with those guided by wires and reflected from the free ends of the wire, the inference being that the velocity of waves along wires is the same as that through the air. This result, which follows from Maxwell's theory, when the wires are not too fine, had been questioned by Hertz on account of some of his experiments on wires.

Detectors.—The use of a detector with a period of vibration of its own thus tends to make the experiments more complicated, and many other forms of detector have been employed by subsequent experimenters. For example, in place of the sparks in air the luminous discharge through a rarefied gas has been used by Dragoumis, Lecher (who used tubes without electrodes laid across the wires in an arrangement resembling that shown in fig. 7) and Arons. A tube containing neon at a low pressure is especially suitable for this purpose. Zehnder (*Wied. Ann.* 47, p. 777) used an exhausted tube to which an external electromotive force almost but not quite sufficient of itself to produce a discharge was applied; here the additional electromotive force due to the waves was sufficient to start the discharge. Detectors depending on the heat produced by the rapidly alternating currents have been used by Paalzow and Rubens, Rubens and Ritter, and I. Klemenčič. Rubens measured the heat produced by a bolometer arrangement, and Klemenčič used a thermo-electric method for the same purpose; in consequence of the great increase in the sensitiveness of galvanometers these methods are now very frequently resorted to. Boltzmann used an electroscope as a detector. The spark gap consisted of a ball and a point, the ball being connected with the electroscope and the point with a battery of 200 dry cells. When the spark passed the cells charged up the electroscope. Ritter utilized the contraction of a frog's leg as a detector, Lucas and Garrett the explosion produced by the sparks in an explosive mixture of hydrogen and oxygen; while Bjerknes and Franke used the mechanical attraction between oppositely charged conductors. If the two sides of the spark gap are connected with the two pairs of quadrants of a very delicate electrometer, the needle of which is connected with one pair of quadrants, there will be a deflection of the electrometer when the detector is struck by electric waves. A very efficient detector is that invented by E. Rutherford (*Trans. Roy. Soc.* A. 1897, 189, p. 1); it consists of a bundle of fine iron wires magnetized to saturation and placed inside a small magnetizing coil, through which the electric waves cause rapidly alternating currents to pass which demagnetize the soft iron. If the instrument is used to detect waves in air, long straight wires are attached to the ends of the demagnetizing coil to collect the energy from the field; to investigate waves in wires it is sufficient to make a loop or two in the wire and place the magnetized piece of iron inside it. The amount of demagnetization which can be observed by the change in the deflection of a magnetometer placed near the iron, measures the intensity of the electric waves, and very accurate determinations can be made with ease with this apparatus. It is also very delicate, though in this respect it does not equal the detector to be next described, the coherer; Rutherford got indications in 1895 when the vibrator was ¾ of a mile away from the detector, and where the waves had to traverse a thickly populated part of Cambridge. It can also be used to measure the coefficient of damping of the electric waves, for since the wire is initially magnetized to saturation, if the direction of the current when it first begins to flow in the magnetizing coil is such as to tend to increase the magnetization of the wire, it will produce no effect, and it will not be until the current is reversed that the wire will lose some of its magnetization. The effect then gives the measure of the intensity half a period after the commencement of the waves. If the wire is put in the coil the opposite way, *i.e.*, so that the magnetic force due to the current begins at once to demagnetize the wire, the demagnetization gives a measure of the initial intensity of the waves. Comparing this result with that obtained when the wires were reversed, we get the coefficient of damping. A very convenient detector of electric waves is the one discovered almost simultaneously by Fessenden (*Electrotech. Zeits.*, 1903, 24, p. 586) and Schlömilch (*ibid.* p. 959). This consists of an electrolytic cell in which one of the electrodes is an exceedingly fine point. The electromotive force in the circuit is small, and there is large polarization in the circuit with only a small current.

When the circuit is struck by electric waves there is an increase in the currents due to the depolarization of the circuit. If a galvanometer is in the circuit, the increased deflection of the instrument will indicate the presence of the waves.

Coherers.—The most sensitive detector of electric waves is the "coherer," although for metrical work it is not so suitable as that just described. It depends upon the fact discovered by Branly (*Comptes rendus*, 111, p. 785; 112, p. 90) that the resistance between loose metallic contacts, such as a pile of iron turnings, diminishes when they are struck by an electric wave. One of the forms made by Lodge (*The Work of Hertz and some of his Successors*, 1894) on this principle consists simply of a glass tube containing iron turnings, in contact with which are wires led into opposite ends of the tube. The arrangement is placed in series with a galvanometer (one of the simplest kind will do) and a battery; when the iron turnings are struck by electric waves their resistance is diminished and the deflection of the galvanometer is increased. Thus the deflection of the galvanometer can be used to indicate the arrival of electric waves. The tube must be tapped between each experiment, and the deflection of the galvanometer brought back to about its original value. This detector is marvellously delicate, but not metrical, the change produced in the resistance depending upon so many things besides the intensity of the waves that the magnitude of the galvanometer deflection is to some extent a matter of chance. Instead of the iron turnings we may use two iron wires, one resting on the other; the resistance of this contact will be altered by the incidence of the waves. To get greater regularity Bose uses, instead of the iron turnings, spiral springs, which are pushed against each other by means of a screw until the most sensitive state is attained. The sensitiveness of the coherer depends on the electromotive force put in the galvanometer circuit. Very sensitive ones can be made by using springs of very fine silver wire coated electrolytically with nickel. Though the impact of electric waves generally produces a diminution of resistance with these loose contacts, yet there are exceptions to the rule. Thus Branly showed that with lead peroxide, PbO_2, there is an increase in resistance. Aschkinass proved the same to be true with copper sulphide, CuS; and Bose showed that with potassium there is an increase of resistance and great power of self-recovery of the original resistance after the waves have ceased. Several theories of this action have been proposed. Branly (*Lumière électrique*, 40, p. 511) thought that the small sparks which certainly pass between adjacent portions of metal clear away layers of oxide or some other kind of non-conducting film, and in this way improve the contact. It would seem that if this theory is true the films must be of a much more refined kind than layers of oxide or dirt, for the coherer effect has been observed with clean non-oxidizable metals. Lodge explains the effect by supposing that the heat produced by the sparks fuses adjacent portions of metal into contact and hence diminishes the resistance; it is from this view of the action that the name coherer is applied to the detector. Auerbeck thought that the effect was a mechanical one due to the electrostatic attractions between the various small pieces of metal. It is probable that some or all of these causes are at work in some cases, but the effects of potassium make us hesitate to accept any of them as the complete explanation. Blanc (*Ann. chim. phys.*, 1905, [8] 6, p. 5), as the result of a long series of experiments, came to the conclusion that coherence is due to pressure. He regarded the outer layers as different from the mass of the metal and having a much greater specific resistance. He supposed that

when two pieces of metal are pressed together the molecules diffuse across the surface, modifying the surface layers and increasing their conductivity.

Generators of Electric Waves.—Bose (*Phil. Mag.* 43, p. 55) designed an instrument which generates electric waves with a length of not more than a centimetre or so, and therefore allows their properties to be demonstrated with apparatus of moderate dimensions. The waves are excited by sparking between two platinum beads carried by jointed electrodes, a platinum sphere is placed between the beads, and the distance between the beads and the sphere can be adjusted by bending the electrodes. The diameter of the sphere is 8 mm., and the wave length of the shortest electrical waves generated is said to be about 6 mm. The beads are connected with the terminals of a small induction coil, which, with the battery to work it and the sparking arrangement, are enclosed in a metal box, the radiation passing out through a metal tube opposite to the spark gap. The ordinary vibrating break of the coil is not used, a single spark made by making and breaking the circuit by means of a button outside the box being employed instead. The detector is one of the spiral spring coherers previously described; it is shielded from external disturbance by being enclosed in a metal box provided with a funnel-shaped opening to admit the radiation. The wires leading from the coherers to the galvanometer are also surrounded by metal tubes to protect them from stray radiation. The radiating apparatus and the receiver are mounted on stands sliding in an optical bench. If a parallel beam of radiation is required, a cylindrical lens of ebonite or sulphur is mounted in a tube fitting on to the radiator tube and stopped by a guide when the spark is at the principal focal line of the lens. For experiments requiring angular measurements a spectrometer circle is mounted on one of the sliding stands, the receiver being carried on a radial arm and pointing to the centre of the circle. The arrangement is represented in fig. 5.

With this apparatus the laws of reflection, refraction and polarization can readily be verified, and also the double refraction of crystals, and of bodies possessing a fibrous or laminated structure such as jute or books. (The double refraction of electric waves seems first to have been observed by Righi, and other researches on this subject have been made by Garbasso and Mack.) Bose showed the rotation of the plane of polarization by means of pieces of twisted jute rope; if the pieces were arranged so that their twists were all in one direction and placed in the path of the radiation, they rotated the plane of polarization in a direction depending upon the direction of twist· if they were mixed so that there were as many twisted in one direction as the other, there was no rotation.

A series of experiments showing the complete analogy between electric and light waves is described by Righi in his book *L'Ottica delle oscillazioni elettriche*. Righi's exciter, which is especially convenient when large statical electric machines are used instead of induction coils, is shown in fig. 6. E and F are balls connected with the terminals of the machine, and AB and CD are conductors insulated from each other, the ends B, C, between which the sparks pass, being immersed in vaseline oil. The period of the vibrations given out by the system is adjusted by means of metal plates M and N attached to AB and CD. When the waves are produced by induction coils or by electrical machines the intervals between the emission of different sets of waves occupy by far the largest part of the time. Simon (*Wied. Ann.*, 1898, 64, p. 293; *Phys. Zeit.*, 1901, 2, p. 253), Duddell (*Electrician*, 1900, 46, p. 269) and Poulsen (*Electrotech. Zeits.*, 1906, 27, p. 1070) reduced these intervals very considerably by using the electric arc to excite the waves, and in this way produced electrical waves possessing great energy. In these methods the terminals between which the arc is passing are connected through coils with self-induction L to the plates of a condenser of capacity C. The arc is not steady, but is continually varying. This is especially the case when it passes through hydrogen. These variations excite vibrations with a period $2\pi\sqrt{LC}$ in the circuit containing the capacity of the self-induction. By this method Duddell produced waves with a frequency of 40,000. Poulsen, who cooled the terminals of the arc, produced waves with a frequency of 1,000,000, while Stechodro (*Ann. der Phys.* 27, p. 225) claims to have produced waves with 300 times this frequency, *i.e.*, having a wave length of about a metre. When the self-induction and capacity are large so that the frequency comes within the limits of the frequency of audible notes, the system gives out a musical note, and the arrangement is often referred to as the singing arc.

Waves in Wires.—Many problems on electric waves along wires can readily be investigated by a method due to Lecher (*Wied. Ann.* 41, p. 850), and known as Lecher's bridge, which furnishes us with a means of dealing with waves of a definite and determinable wave-length. In this arrangement (fig. 7) two large plates A and B are, as in Hertz's exciter, connected with the terminals of an induction coil; opposite these and insulated from them are two smaller plates D, E, to which long parallel wires DFH, EGJ are attached. These wires are bridged across by a wire LM, and their farther ends H, J, may be insulated, or connected together, or with the plates of a condenser. To detect the waves in the circuit beyond the bridge, Lecher used an exhausted tube placed across the wires, and Rubens a bolometer, but Rutherford's detector is the most convenient and accurate. If this detector is placed in a fixed position at the end of the circuit, it is found that the deflections of this detector depend greatly upon the position of the bridge LM, rising rapidly to a maximum for some positions, and falling rapidly away when the bridge is displaced. As the bridge is moved from the coil end towards the detector the deflections show periodic variations, such as are represented in fig. 8 when the abscissae represent the deflections of the detector and the ordinates the distance of the bridge from the ends D, E. The maximum deflections of the detector correspond to the positions in which the two circuits DFLMGE, HLMJ (in which the vibrations are but slightly damped) are in resonance. For since the self-induction and resistance of the bridge LM is very small compared with that of the circuit beyond, it follows from the theory of circuits in parallel that only a small part of the current will in general flow round the longer circuit; it is only when the two circuits DFLMGE, HLMJ are in resonance that a considerable current will flow round the latter. Hence when we get a maximum effect in the detector we know that the waves we are dealing with are those corresponding to the free periods of the system HLMJ, so that if we know the free periods of this circuit we know the wave length of the electric waves under consideration. Thus if the ends of the wires H, J are free and have no capacity, the current along them must vanish at H and J, which must be in opposite electric condition. Hence half the wave length must be an odd submultiple of the length of the circuit HLMJ. If H and J are connected together the wave length must be a submultiple of the length of this circuit. When the capacity at the ends is appreciable the wave length of the circuit is determined by a somewhat complex expression. To facilitate the determination of the wave length in such cases, Lecher introduced a second bridge L'M', and moved this about until the deflection of the detector was a maximum; when this occurs the wave length is one of those corresponding to the closed circuit LMM'L', and must therefore be a submultiple of the length of the circuit. Lecher showed that if instead of using a single wire LM to form the bridge, he used two parallel wires PQ, LM, placed close together, the currents in the further circuit were hardly appreciably diminished when the main wires were cut between PL and QM. Blondlot used a modification of this apparatus better suited for the production of short waves. In his form (fig. 9) the exciter consists of two semicircular arms connected with the terminals of an induction coil, and the long wires, instead of being connected with the small plates, form a circuit round the exciter.

As an example of the use of Lecher's arrangement, we may quote Drude's application of the method to find the specific induction capacity of dielectrics under electric oscillations of varying frequency. In this application the ends of the wire are connected to the plates of a condenser, the space between whose plates can be filled with the liquid whose specific inductive capacity is required, and the bridge is moved until the detector

at the end of the circuit gives the maximum deflection. Then if λ is the wave length of the waves, λ is the wave length of one of the free vibrations of the system HLMJ; hence if C is the capacity of the condenser at the end in electrostatic measure we have

$$\frac{\cot(2\pi l/\lambda)}{(2\pi l/\lambda)} = \frac{C}{C'l}$$

where l is the distance of the condenser from the bridge and C' is the capacity of unit length of the wire. In the condenser part of the lines of force will pass through air and part through the dielectric; hence C will be of the form $C_0 + KC_1$ where K is the specific inductive capacity of the dielectric. Hence if l is the distance of maximum deflection when the dielectric is replaced by air, l' when filled with a dielectric whose specific inductive capacity is known to be K', and l'' the distance when filled with the dielectric whose specific inductive capacity is required, we easily see that—

$$\frac{\cot(2\pi l/\lambda) - \cot(2\pi l'/\lambda)}{\cot(2\pi l/\lambda) - \cot(2\pi l''/\lambda)} = \frac{1-K'}{1-K}$$

an equation by means of which K can be determined. It was in this way that Drude investigated the specific inductive capacity with varying frequency, and found a falling off in the specific inductive capacity with increase of frequency when the dielectrics contained the radicle OH. In another method used by him the wires were led through long tanks filled with the liquid whose specific inductive capacity was required; the velocity of propagation of the electric waves along the wires in the tank being the same as the velocity of propagation of an electromagnetic disturbance through the liquid filling the tank, if we find the wave length of the waves along the wires in the tank, due to a vibration of a given frequency, and compare this with the wave lengths corresponding to the same frequency when the wires are surrounded by air, we obtain the velocity of propagation of electromagnetic disturbance through the fluid, and hence the specific inductive capacity of the fluid.

Velocity of Propagation of Electromagnetic Effects through Air.—The experiments of Sarasin and De la Rive already described have shown that, as theory requires, the velocity of propagation of electric effects through air is the same as along wires. The same result had been arrived at by J. J. Thomson, although from the method he used greater differences between the velocities might have escaped detection than was possible by Sarasin and De la Rive's method. The velocity of waves along wires has been directly determined by Blondlot by two different methods. In the first the detector consisted of two parallel plates about 6 cm. in diameter placed a fraction of a millimetre apart, and forming a condenser whose capacity C was determined in electromagnetic measure by Maxwell's method. The plates were connected by a rectangular circuit whose self-induction L was calculated from the dimensions of the rectangle and the size of the wire. The time of vibration T is equal to $2\pi\sqrt{(LC)}$. (The wave length corresponding to this time is long compared with the length of the circuit, so that the use of this formula is legitimate.) This detector is placed between two parallel wires, and the waves produced by the exciter are reflected from a movable bridge. When this bridge is placed just beyond the detector vigorous sparks are observed, but as the bridge is pushed away a place is reached where the sparks disappear; this place is distance $2/\lambda$ from the detector, when λ is the wave length of the vibration given out by the detector. The sparks again disappear when the distance of the bridge from the detector is $3\lambda/4$. Thus by measuring the distance between two consecutive positions of the bridge at which the sparks disappear λ can be determined, and v, the velocity of propagation, is equal to λ/T. As the means of a number of experiments Blondlot found v to be $3{\cdot}02\times10^{10}$ cm./sec., which, within the errors of experiment, is equal to 3×10^{10} cm./sec., the velocity of light. A second method used by Blondlot, and one which does not involve the calculation of the period, is as follows:—A and A' (fig. 10) are two equal Leyden jars coated inside and outside with tin-foil. The outer coatings form two separate rings a, a_1; a', a'_1, and the inner coatings are connected with the poles of the induction coil by means of the metal pieces b, b'. The sharply pointed conductors p and p', the points of which are about ½ mm. apart, are connected with the rings of the tin-foil a and a', and two long copper wires pca, $p'c'a'_1$, 1029 cm. long, connect these points with the other rings a_1, a_1'. The rings aa', a_1a_1', are connected by wet strings so as to charge up the jars. When a spark passes between b and b', a spark at once passes between pp', and this is followed by another spark when the waves travelling by the paths $a_1\,cp$, $a'_1c'p'$ reach p and p'. The time between the passage of these sparks, which is the time taken by the waves to travel 1029 cm., was observed by means of a rotating mirror, and the velocity measured in 15 experiments varied between $2{\cdot}92\times10^{10}$ and $3{\cdot}03\times10^{10}$ cm./sec., thus agreeing well with that deduced by the preceding method. Other determinations of the velocity of electromagnetic propagation have been made by Lodge and Glazebrook, and by Saunders.

On Maxwell's electromagnetic theory the velocity of propagation of electromagnetic disturbances should equal the velocity of light, and also the ratio of the electromagnetic unit of electricity to the electrostatic unit. A large number of determinations of this ratio have been made:—

Observer.	Date.	Ratio $10^{10}\times$.
Klemenčič	1884	3·019 cm./sec.
Himstedt	1888	3·009 cm./sec.
Rowland	1889	2·9815 cm./sec.
Rosa	1889	2·9993 cm./sec.
J. J. Thomson and Searle	1890	2·9955 cm./sec.
Webster	1891	2·987 cm./sec.
Pellat	1891	3·009 cm./sec.
Abraham	1892	2·992 cm./sec.
Hurmuzescu	1895	3·002 cm./sec.
Rosa	1908	2·9963 cm./sec.

The mean of these determinations is $3{\cdot}001\times10^{10}$ cm./sec., while the mean of the last five determinations of the velocity of light in air is given by Himstedt as $3{\cdot}002\times10^{10}$ cm./sec. From these experiments we conclude that the velocity of propagation of an electromagnetic disturbance is equal to the velocity of light, and to the velocity required by Maxwell's theory.

In experimenting with electromagnetic waves it is in general more difficult to measure the period of the oscillations than their wave length. Rutherford used a methad by which the period of the vibration can easily be determined; it is based upon the theory of the distribution of alternating currents in two circuits ACB, ADB in parallel. If A and B are respectively the maximum currents in the circuits ACB, ADB, then

$$\frac{A}{B} = \sqrt{\frac{S^2+(N-M)^2p^2}{R^2+(L-M)^2p^2}}$$

when R and S are the resistances, L and N the coefficients of self-induction of the circuits ACB, ADB respectively, M the coefficient of mutual induction between the circuits, and p the frequency of the currents. Rutherford detectors were placed in the two circuits, and the circuits adjusted until they showed that A = B; when this is the case

$$p^2 = \frac{R^2-S^2}{N^2-L^2-2M(N-L)}.$$

If we make one of the circuits, ADB, consist of a short length of a high liquid resistance, so that S is large and N small, and the other circuit ACB of a low metallic resistance bent to have considerable self-induction, the preceding equation becomes approximately $p = S/L$, so that when S and L are known p is readily determined. (J. J. Th.)

ELECTRIFICATION OF INDUSTRY. There are three considerations involved in the application of the electric drive in industry, all of which need careful attention if the work is to be fully successful. These are (1) the motor; (2) the control gear; (3) the close co-ordination of these two components with the apparatus to be driven. Progress has been made during recent years particularly as a result of the great developments in auto-

matic and heavy duty control gear, and in the co-ordination of all the components into a harmonious unit. The author, therefore, proposes to begin by considering briefly the chief types of motor employed for industrial drive, and the most recent forms of control gear by which their utility has been extended. The electrification of specific industries and equipment will then be considered.

ELECTRICAL EQUIPMENT

Electric Motors.—The principal industrial motors are as follows: (*a*) Direct current—series, shunt, compound. (*b*) Alternating current—squirrel-cage induction, squirrel-cage induction "across-the-line" type, slip-ring induction, synchronous. For a description of the principles and capabilities of these, the reader is referred to the article on ELECTRIC MOTORS.

ELECTRIC CONTROL GEAR

The principal control operations required by an industrial motor are starting, stopping, speed adjustment; and protection of the machine under all circumstances. The control gear may be hand-operated or automatic, there being varying of automatic devices, according to the amount of responsibility that may still be reposed in the operator. For example, the apparatus may be controlled by automatic switches, or "contactors," every one of which may, however, act only at the will of an attendant, who is provided with small "pilot" switches or a "master controller" for governing the movements of the units that actually make and break the main circuit. Again, the rate of acceleration only may be decided automatically, in accordance with the loading conditions; and thus the motor safeguarded while at the same time all unnecessary delay is avoided. Finally, the whole of an elaborate series of operations may be effected solely at the instance of a set of relays without any human guidance whatever.

The two principal control methods that combine to bring about the complete government of an electric motor are, first, the making and breaking of circuits, and secondly the variation of the voltage applied to a winding, such as that of an armature, rotor or stator. The latter function may be achieved by varying the amount of resistance in series or parallel with the winding, and this again usually requires the making and breaking of auxiliary circuits by exactly the same means as were needed for the former function. This function may also be performed through the use of an auto-transformer for starting induction motors on voltages lower than line voltage. Voltage variation may however be performed directly and with greater efficiency, for example by regulating the field of a generator, and thus the use of resistors may be largely avoided in heavy equipments.

The chief types of control apparatus may thus be tabulated as follows: (*a*) Manual apparatus—(1) switch type, (2) face-plate type, (3) drum type, (4) liquid type. (*b*) Automatic apparatus—(1) contactor type, (2) variable voltage type.

Manual Apparatus.—The simplest piece of manually operated control gear is of course the switch, in which one or more pairs of contacts can be brought together by hand. Of the various patterns, the knife switch is the most common, enabling an efficient contact to be made by means of a simple and compact device. In its usual form, however, it does not lend itself to frequent use (such as once every 10 sec.), and it is generally employed as a main isolating device for putting the whole equipment into commission at the beginning of the working period.

A single switch may be employed for starting any induction motor, or a D.C. shunt motor up to ½ or 1 h.p., a compound motor up to about 2 h.p., and a series motor up to 8 horse-power. Above these sizes, the rush of current due to the low armature resistance and the absence of counter E.M.F. when at rest necessitates the use of a preliminary stage of resistance. "Push" switches are very useful for starting the smallest motors and for controlling small currents generally. Large oil-immersed switches may be used for making and breaking the stator circuits of high-voltage (*e.g.*, 3,000 volt) induction motors or of lower voltage motors of large rating where the currents are of considerable magnitude.

The face-plate starter or controller is really a radial distributing switch for cutting out successive steps of resistance. It is a cheap and compact device, and enables a comparatively heavy contact pressure to be maintained without demanding a corresponding force to move it. Nearly all manual starters for D.C. motors up to 100 h.p., and most A.C. resistance starters for small motors are of this type; but it is adapted to the simplest changes in the circuit, and hence starters for squirrel-cage motors

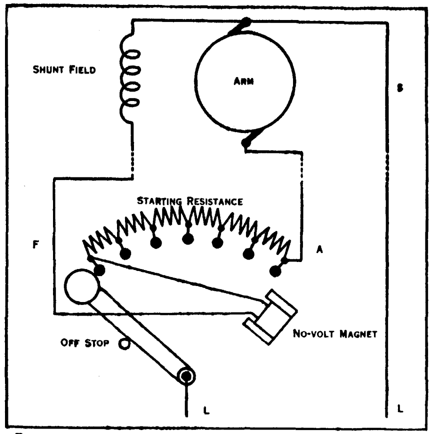

FIG. 1.—DIAGRAM SHOWING CONNECTION FOR FACE-PLATE STARTER

which aim at reducing the voltage to the stator by other than resistance means almost invariably employ another pattern. It is also not adopted for robust service, *i.e.*, for the frequent breaking of large currents, and it is usually designed to *make* the currents only, all breaking being done by a knife switch before the starter arm is automatically released by a "no-volt" or "under-voltage" retaining magnet.

The method of connection of a typical face-plate starter is indicated in fig. 1, in which it is shown connected to a D.C. shunt motor. A compound motor would have a series field located at *S*, while a series motor would only have the latter, the lead that includes the shunt winding in the figure being omitted and the no-volt coil connected across the line in series with an appropriate resistance.

When used for almost any of the various industrial purposes, the face-plate should be protected by enclosing it with a metal cover.

For frequent service, heavier duty, and more elaborate changes of circuit, a drum starter or controller is used, in which the moving contacts are sector-shaped and are clamped on to a square spindle covered with insulation; and the fixed contacts are "fingers" with heavy copper renewable tips forced against the sectors by spring pressure. A powerful magnetic blow-out is always fitted for all but the smallest sizes; and a locating "star-wheel" device, which enables the operator to halt the contacts exactly in engagement.

A typical D.C. drum controller diagram corresponding in most respects to the face-plate scheme in the last figure is shown in fig. 3; but the drum sectors are duplicated to give both forward and reverse running from the same handle, the line connections being made and reversed by the section enclosed in the lower chain-dotted outline. As before the motor parts are shown in place on a reduced scale, and either field winding may be omitted. The sectors are represented by horizontal strips and the fingers by large dots. As is necessary with reversing installations, the shunt field is shunted by a non-inductive resistance. Other and somewhat more elaborate drum diagrams are shown in figs. 4 and 7.

Drum starters (also called compensators or auto-starters) are also used for squirrel-cage motors when (as is usually the case for motors over 5 h.p.) local regulations require starting at reduced voltage, obtained by the use of a step-down transformer, or by connecting the stator windings first in star and then in mesh.

Liquid rheostats are suitable for use with any type of motor, but especially with those over about 100 h.p. and which start under load for which the previously described manual equipment is not

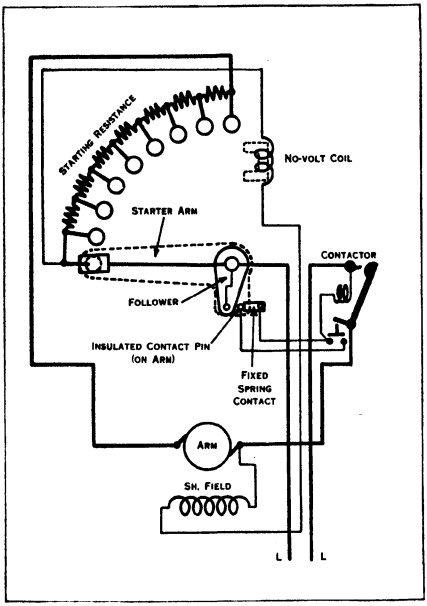

FIG. 2.—DIAGRAM SHOWING INCHING STARTER AND PARTS

well adapted. They are especially adapted to the absorption of large amounts of power.

In all but the largest, the "dippers," or moving contacts, are moved in and out of the liquid; but in the largest models (viz., up to and exceeding 2,000 h.p.), the plates are fixed and the liquid is caused to rise by means of an electrically driven pump. When the apparatus is used for controller duty, cooling pipes are immersed in the liquid. The weir-type controller, in which the height of the liquid is regulated by the moving of a weir mechanically connected to the driver's lever, is a variant of the rising liquid starter. The principal advantages of the liquid type are the indestructibility of the resistor, smoothness of acceleration, cheapness and suitability for the largest sizes. Chemical action is absent with alternating currents.

Automatic Apparatus.—The contactor, or magnet switch, is a marked advance in control equipment used in industrial electrification during recent years, especially for horse-powers up to 500. It is a magnetically operated switch, and its most usual forms cover voltages up to 600 and currents up to 1,000 amperes, although ratings up to 11,000 volts and 5,000 amperes are in existence. For D.C. circuits, single-pole models are the rule, but for A.C., as many as four, or even more, moving contacts are mounted upon the one rocker shaft. The contacts are usually of a flat horn shape, engaging with a rolling motion and making a line contact, and breaking circuit between the poles of a powerful magnetic blow-out.

Contactors may be normally-open or normally-closed, the contacts in the latter case being pulled open by the energizing of the coil. D.C. models are sometimes designed to hold themselves open until the current in the main circuit falls to a given value, when they close: this characteristic being required for automatic acceleration by the cutting out of resistance. Series and shunt lock-out contactors belong to the latter category.

Fully automatic characteristics are given to contactor installations by means of relays, the chief varieties of which are included in the following list: Current-limit, time limit, float, pressure, overload, low-voltage, inching, torque, step-back, change-over, field-accelerating, field-braking and field-protection relays. Of these, the first two are the most important, since they provide for automatic acceleration without requiring lock-out contactors, the use of which has its limitations. Current-limit relays permit their contacts to close when the peak current, due to the switching-in of the motor or the cutting out of a previous step of resistance, falls to a predetermined value, whereupon the next accelerating contactor is caused to close. Time-limit relays bring about closing of the accelerating units at definite time intervals. The former method is appropriate for heavy and fluctuating duty, such as rolling-mill auxiliaries and general industrial control; and the latter for such loads as air-compressors, pumping, ventilating, etc. Float and pressure relays are employed for starting and stopping the operations for the latter type of load.

Examples of the various types and arrangements of contactors and relays will be given in succeeding sections. It will be sufficient here to indicate that most contactor diagrams consist of a line group and an accelerating group, which are connected in series in the case of D.C. motors, but form the stator and rotor circuits in the A.C. cases.

Auxiliary switches, such as push-switches, master-switches and master-controllers, are employed in the handling and general control of contactor installations; and interlocks, both mechanical and electrical, are added to prevent the consequences of improper

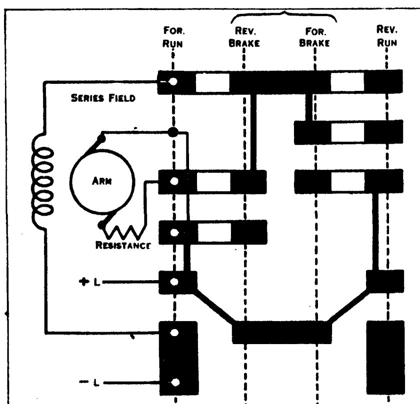

FIG. 3.—REVERSING DRUM CONTROLLER

operation, *e.g.*, two contactors of opposite polarity making contact with the one lead.

Variable voltage control is nearly always effected by use of a motor-generator, set apart for the supply of the D.C. motor to be controlled, and caused to develop the voltage required at any stage by virtue of the field regulation of the generator. The arrangement is shown in its fundamental form in fig. 5 and is usually termed the "Ward-Leonard system."

An A.C. supply is presupposed, driving the induction motor of

the motor-generator, which also often includes an exciter for the two D.C. fields, though in large sets this may be a separate unit. The main driving motor is shown on the right, and this is started, stopped, reversed and regulated at any speed by the corresponding variation of the generator voltage by means of the reversing potentiometer-type field rheostat. The scheme will be seen to dispense with resistors in the main circuit, all switching and adjustment being carried out upon the exciting current. Since the field flux of even a moderate-sized dynamo changes gradually, the control is remarkably smooth and sensitive. Ward-Leonard control is especially appropriate for securing very wide speed regulation, and for use where preliminary creeping speeds are required.

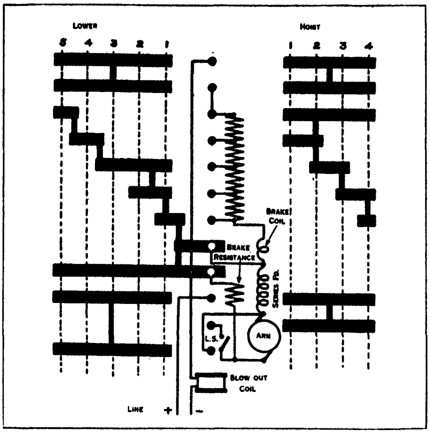

FIG. 4.—DIAGRAM OF DRUM CONTROLLER FOR CRANE

If the induction motor is equipped with a fly-wheel and given a variable speed characteristic, by connecting a fixed resistance in its rotor circuit, or preferably by employing a variable slip-regulator which introduces resistance in proportion to the overland peaks, the motor-generator is now able to store energy during light-load periods and to give it back during overloads. This is called the "Ilgner system," and possesses the great advantage of much reducing the maximum demand on the line. It also renders a much smaller induction motor suitable. Large rolling-mill drives are usually of this type.

Other methods of producing partial voltages without the use of resistance, which are suitable for small powers, are the series-parallel system employing two motors, and the multi-wire system, in which more than one voltage is given by the factory distribution. These methods however have only a limited application for industrial work.

THE ELECTRIFICATION OF FACTORIES

Advantages of Electrification.—In no situation have the benefits accruing from industrial electrification been more important than in the factories, where the amelioration of the working conditions has been able to affect the lives of so great a portion of the population. Yet through lack of a sufficiently disseminated understanding as to the advantages thus held out, the improvement is far from being as complete as is possible, either as regards economy of working or convenience. There is much to gain, therefore, from a consideration of the available benefits, and the means whereby these may be fully secured.

If the old method of single-unit drive for an entire factory by means of a steam or internal-combustion engine and lineshafting are contrasted with employing electrical drive, two changes in principle are found to take place. First, it is not now compulsory to lay down an engine-room at all, and the capital so locked up may be devoted to an extension of the factory proper. Secondly, the transmission of power about the works is effected electrically, and thus invisibly, safely and economically, instead of by a mass of shafts and belting which is so conspicuous a feature in the older order of things. At once, without going into details, several important advantages are evident.

First, the saving in running cost is great. The average expense of supplying a works with motive power by means of a steam engine and the usual belts and shafting, assumed to be in good condition, may be taken as 2% of the value of the output. This figure may be greatly reduced if the machines be driven in groups by motors of, say, 10 to 20 h.p.; while if all the belts and shafts are dispensed with, and a motor installed for every machine, the cost is still further reduced.

Secondly, the full consequences of a breakdown in the motive power or in an important link in the transmission are greatly reduced. Thirdly, the power supply is now much more direct, and is therefore subject to less fluctuation. Fourthly, the interior of the factory is transformed and improved in every detail by the absence of the mechanical transmission; while all the additional advantages of electrical working are provided. The individual gains comprehended in the last category are worth enumerating in some detail:—

(1) The factory is made more fit to work in; it has gained greatly in cleanliness, wholesomeness, safety, illumination and consequently in the standard of work that can be turned out in it. (2) Belt troubles are done away with. (3) The factory structure may be more lightly and cheaply constructed, as it does not have to withstand the stresses of belt drive. (4) Factory transport is very much facilitated by the possibility of installing overhead cranes wherever required. (5) The whole of a shop need not be run during overtime; while with individual drive only those machines actually required are actuated. (6) Fly-wheel operation at variable speed may be employed, without special arrangements, for fluctuating loads. (7) A greater amount of power is available at individual machines, giving a greater overload capacity. (8) With individual drive the closest and the most constant speed regulation is possible for every machine, while variable speed may be obtained in any number of steps by field adjustment, with greater ease and exactness than is possible by mechanical means. (9) The difficulties of installing line shafting in concrete buildings are avoided.

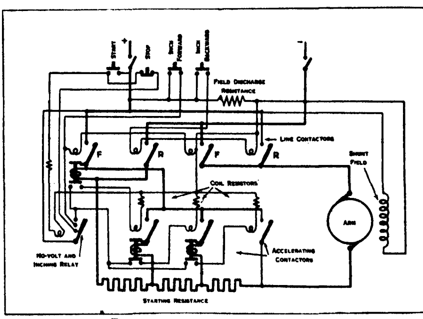

FIG. 5.—AUTOMATIC CONTROL GEAR

Motors may be installed on machines at the factory of the machine builder, thus insuring the correct motor for the application. The initial investment in power-driving equipment is higher in the case of a factory using individual drive than in one using the older method of line-shaft drive. The advantages of the former, however, so unquestionably overbalance the latter that there is today practically no justification for the older method.

In designing the electrified factory, the best results will be achieved by bearing these possibilities in mind, and taking pains

to secure them to the full, and at the same time avoiding the introduction of any fresh drawbacks not possessed by the old scheme. The latter category might include, if the installation were carelessly effected, electrical dangers to the building or workpeople, and risk of breakdown through damp, dirt, mechanical weakness or inexpert handling. Details of design are considered below.

Size of Groups.—As the advantages that have been enumerated are the more fully experienced the more nearly the ideal of individual drive is reached, it is obvious that the size of the groups should be made as small as practicable. All authorities are agreed that the larger equipment, such as punching and shearing machines, large planers, borers, lathes, etc., should be individually driven; but many still consider that the high cost of numerous small motors as compared with a single large one is not justified. On the other hand, many others, who are more willing to break away from the old traditions, maintain that individual drive is preferable in every case, even with the smallest machines; and the author inclines to the latter view. However, the present section will deal with those cases of group and individual drive in which special control gear is not required, and the more advanced cases of automatic individual control will be considered under MACHINE TOOLS.

Motors.—From what has already been said it is evident that line shafting, requiring as it does a constant speed, should be operated either by shunt or squirrel-cage induction motors, depending on whether D.C. or A.C. is available. If there is a choice of system, the A.C. is preferable, on account of its smaller cost and greater robustness. Care should be taken to locate the motors in positions where they are out of harm's way and do not use up valuable space, such as on the driven machines themselves, or upon the ceiling, walls or columns of the building. Many machine-tool makers provide a seating for a motor as a matter of course, *e.g.*, above the headstock in the case of a lathe; and it is to be hoped that it will not be long before the practice becomes general.

Control Gear.—The control gear simply consists of a starter, sometimes alone (as with A.C.) and sometimes accompanied by a knife switch and fuses. For individual drive, such as in textile factories, all that is often needed is a simple on-and-off switch, such as a push switch, or one of a small drum ("loom") type, mounted at a place convenient to the operator's hand. The larger and more complicated apparatus may be mounted on the wall or column, or may be of the "pillar" or "pedestal" type. All should be ironclad and as fool-proof as possible, and should be easily accessible to the operator. For starting comparatively large motors driving line shafting, an "inching" starter mounted in a control pillar has the great advantage of reliability under inexpert handling. As illustrated in the diagram forming fig. 2, the contact arm may with impunity be "backed" in a way that would ruin the studs of an ordinary starter; for here the loose "follower" arm will lag behind and cause the circuit to be broken effectively at the contactor. Such pillars are usually provided also with overload relays, which at once open the contactor if the arm is moved over too rapidly, or if similar misuse occurs.

MACHINE TOOLS

Electrical Design.—The great importance of designing an electrically-driven apparatus as a harmonious unit, and not as an aggregate of a machine, a motor and a more or less unsuitable starter connected by wiring but otherwise not co-ordinated in any way, applies with special force to machine tools.

The policy should be rigorously observed of making both motor and control gear as much part of the machine tool as any of its mechanical components. Moreover, the handle controlling the movements of the motor should be located among the other handles and in a position as convenient to the operator as possible, and the whole scheme should be so designed that this handle needs no greater care in its operation than any of the purely mechanical levers. The operation of machine tools will be considered under the following headings:—

(1) *Small-power Tools.*—Many tools, such as portable drillers, grinders, etc., as well as small bench drillers and similar machines, are driven by small motors that require only a simple switch for setting them in motion. Portable tools in particular are usually equipped with a series-wound "universal" motor suitable for D.C. or A.C. of any periodicity, and having a capacity seldom exceeding 1 horse-power. Tools having induction motors not exceeding 2 h.p. also come under this category, as do larger induction motors when the supply authority does not insist on star-delta or auto transformer starting. A robust push switch or simple drum switch is quite appropriate here. A no-volt release is a desirable addition, but is seldom fitted for the smaller examples.

(2) *Auxiliary Drives.*—A slightly more elaborate installation is required for performing the auxiliary functions of a large machine tool, such as raising and lowering the tool-head, radial arm or cross-bar of large boring mills, planers and radial drillers. Series D.C. or squirrel-cage A.C. motors are usually employed for these purposes, of about 5 to 10 horse-power.

The D.C. motor is somewhat the more convenient on account of its self-braking capabilities; a compact drum controller may be employed which completely governs such a motor without requiring a magnetic blow-out, or more than the single small resistor. There are four positions of the drum in all, but these in reality constitute three for each direction of rotation. When the cylinder is moved to the position at one end or to that at the opposite extremity of its movement, the armature is connected across the line in series with the resistance for forward or reverse running. When it is moved one step back, the line is disconnected and the motor "drifts"; but upon a further movement being made, the armature and resistance are connected to the field in the correct direction to drive a powerful current through the circuit, bringing about a quick stop by "dynamic" braking.

(3) *Small Lathes, etc.*—Many machines of moderate horse-power such as small lathes, shapers, drillers, etc., that require infrequent starting and no reversing or braking, and usually no speed control, are driven by shunt or squirrel-cage motors and simple ironclad starters. The latter are usually hand-operated, but automatic starting is preferable, especially in the D.C. case. A simple scheme would consist of start and stop push buttons, or other form of pilot switch, operating a 25 ampere line contactor followed by one or two accelerating contactors of similar capacity.

The most convenient method of operating a manual drum-starter, or a master switch for contactor gear, when employed for lathe control, is to mount it horizontally at the end of a spline shaft which is rotated by a lever situated upon the tool saddle.

(4) *Radial Drillers and Screwing Machines.*—Machines of moderate horse-power (*e.g.*, 5 to 10 h.p.) that need repeated starting and reversing and must be lever-controlled, but do not call for special braking or speed regulation, mostly require automatic control gear and are represented by a radial driller having a built-in compound motor. The controller may be built into a pocket in the radial arm, or may be mounted out of the way at the back of the arm, and operated from the handle at the tool-head by means of bevel gearing. Great simplicity may be given to the control scheme by the use of a reversing drum switch for making, breaking and reversing the line connections, the first current-limit relay being mechanically interlocked with the shaft of the drum in such a way that its armature is released as soon as the drum contacts have met; and the acceleration then proceeds as usual. Upon the drum switch being completely reversed, the motor is brought to rest by "plugging" and immediately accelerated in the opposite direction.

(5) *Boring Mills.*—Machines of fairly large horse-power, such as boring mills, that require to be started infrequently in one direction only, but must be capable of being inched both forward and back for setting up, require automatic push-button operation. Shunt-wound D.C. or slip-ring induction motors of about 25 h.p. are used for this purpose, a suitable control scheme, designed for a D.C. motor, being shown in fig. 2. This gear is housed in a control pillar located near the motor and is interesting in that

it illustrates the application of inching buttons and no-volt protection to a scheme. The push buttons are all of the "spring-off" type, making only momentary contact.

Direct current equipments sometimes have speed control by field regulation, and dynamic braking to render inching more effective.

(6) *Wheel Lathes.*—Large lathes for wheel and tyre turning must have provision for slowing down at "hard spots," or for turning cranks. A push button is usually located on the head-stock for effecting the slow-down, and this is accomplished by the cutting out of field resistance with a variable speed motor or else by the cutting in of the armature or rotor-starting resistance. D.C. compound or slip-ring induction motors of about 15 to 40 h.p. are employed, the compounding in the former case being required for steadying the running when operating with a weak field.

(7) *Large Planers, Slotters and Shapers.*—Reciprocating machine tools of fairly large power, such as planers, slotters, shapers, etc., that require reversal of the motor at the beginning and end of each stroke, demand a special form of motor and the most advanced form of contactor gear. There are three grades of planer, which may be taken as typical, viz., plate-edge planers, ordinary planers with a speed range not exceeding 3:1, and those with a range of about 10:1. The first cuts in both directions at an even speed, and problems as to reversal and braking are less severe than with the other forms. The latter have a shorter stroke, must reverse very quickly and accurately and therefore need dynamic braking, and nearly always need an accelerating arrangement for saving time when the tool is "cutting air" and for permitting the tool to enter the metal slowly when planing sheets. In general, a special "planer" motor is used, having a low diameter armature to decrease the stored energy and thus secure quick reversal. Owing to ease of dynamic braking and speed control, D.C. compound motors are at an advantage.

Both A.C. and D.C. motors are used for plate edge planers. The control gear is usually operated by a stationary switch opened and closed by an endless cord. For ordinary planers with a 3:1 speed range, a D.C. compound motor of about 20 h.p. is used, controlled by contactor gear having a single accelerating contactor, push buttons for starting and stopping and inching both ways, double-throw dynamic-braking reversing contactors, two-field rheostats for cutting and return strokes respectively, and an auxiliary switch turned "on" and "off" by the platen for bringing about quick speed during a portion of the cutting stroke by temporarily changing over to the return-stroke rheostat.

For all A.C. equipments, and for D.C. circuits when a greater speed range than about 3:1 is required, the Ward-Leonard type of control is used. Instead of the potentiometer regulator being employed, two ordinary rheostats are provided, for cutting and return strokes respectively, and a switch actuated by the platen changes over from one to the other.

In a 10:1 range planer, it is usual to obtain a 2:1 adjustment of the return speed by field regulation of the reversing motor, and a 5:1 adjustment of the cutting speed by means of the generator field rheostat.

ELECTRIFICATION OF STEELWORKS

The application of the electric drive to steelworks forms a good example of the more recent advances into the field of heavy industries, where conditions were for many years most unfavourable to the use of the electric motor. The high acceleration required, the violent fluctuation of the load, and the huge power demand, all taxed the mechanical and electrical robustness of the motor to the limit, in a situation where continuity of service was all-important; while the prevalent high temperatures and the all-pervading grit strongly militated against the durability of insulation and wearing parts. In spite of all these difficulties, electricity has won the day, and steam drive has been forced into obsolescence, by virtue of the developments in control methods that have been described in the first section, aided by the production of the "mill" type of motor.

The chief pieces of steelworks equipment that call for comment are the following: (*a*) Furnace hoists; (*b*) main rolling-mill drives—large main rolls, requiring up to about 20,000 h.p.; smaller mills, requiring up to about 500 h.p.; (*c*) mill auxiliaries—live rolls, lifting and tilting tables, screw-downs, manipulators, side-guards; (*d*) transport equipment—various highly developed

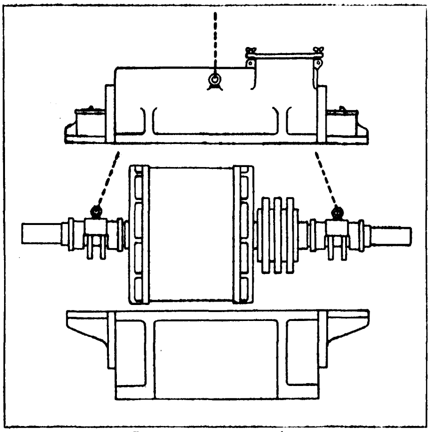

FIG. 6.—MILL TYPE MOTOR

cranes; (*e*) other equipment; *e.g.*, hot saws, air compressors, etc.

Motors.—The special motors may be divided into two classes. First, there are the very large units, up to about 20,000 h.p. instantaneous rating, operated by Ilgner sets. These are mostly double-armature machines, being really designed as twinned units with the object of keeping the diameter and therefore the inertia low, to facilitate quick reversal. As regards shaft diameter and mechanical design generally, they are made robust; but the treatment accorded to them is not so severe as in the case of the smaller auxiliaries. Secondly, there are the motors used for the latter purpose, which are designed to withstand the roughest mechanical and electrical conditions experienced in any situation. The "mill type," illustrated in fig. 6, was developed for this purpose, and is made for both D.C. and A.C. It is totally enclosed, and the frame is split in halves horizontally to facilitate rapid opening up. The shaft is made to project from each bearing, so that the rotor or the whole machine may be reversed endwise if the driving end should be twisted off. Full use has been made of eye-bolts on bearing bushes and frame to render the most rapid refitting possible.

Control Gear.—Ward-Leonard (including Ilgner) and contactor control divide the field between them, and are designed for operation by unskilled attendants whose faculties are concentrated on the actual work that is in progress. The various types of installation are most conveniently dealt with in connection with the equipment to be driven.

Furnace Hoists.—Simple push-buttons or pull-lever operation and accurate decking are the essentials for furnace hoist control, the conditions for which are not so strenuous as they are in the actual mill. The power required is in the vicinity of 100 h.p., and is provided by compound motors with "straight" contactor control gear for D.C. circuits, and by Ward-Leonard gear when the supply is A.C. A typical A.C. equipment is illustrated in fig. 7. It will suffice to explain that the regulator is operated by one of two cams, for up and down motions respectively, and the travel is started by changing the drum over from one cam to the other by means of a lever.

Rolling Mills.—Large reversing main rolls are driven by

Ilgner gear, the scheme being broadly as in fig. 7, with the addition of a slip regulator and fly-wheel to the induction motor. Particulars of a typical large set are as follows: Mill (reversing) motor—6,000 to 18,000 h.p. at 1,600 volts, twin-armature type. Generators—three in series, 4,500 kw. total continuous rating. Induction motor—3,000 h.p., 2,750 volts, three-phase.

The comparatively small size of the induction motor will afford an indication as to the equalizing of the load due to the fly-wheel

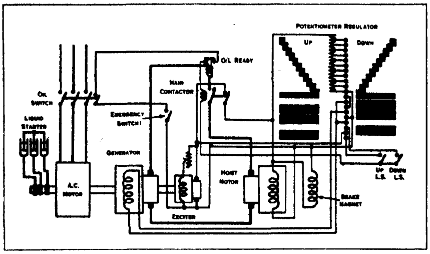

FIG. 7.—DIAGRAM OF MOTOR-GENERATOR CONTROL SCHEME FOR FURNACE HOIST

and slip regulator. Something like a quarter of the whole input is stored and returned by this wheel in the form of regenerative braking.

Small main rolls and many large non-reversing (including three-high) mills are driven direct by induction motors, with or without gearing. For non-reversing (continuous) mills, a fly-wheel is usually mounted on the mill shaft or that of the motor. The control gear is of the contactor type, with slip-regulator if a fly-wheel is employed.

Auxiliaries.—It is for the drive of the auxiliaries, requiring from 50 to 100 h.p., that the mill type of motor was developed. The policy as to control gear is to keep it as simple as possible, and series or induction motors are in most general use, with plain reversing contactor equipment, braking being typically by plugging. For screw-downs and similar equipment, a solenoid brake may be added.

The operation of a lifting table is an exacting procedure, and requires a special control system.

Cranes and Machine Tools.—Except for the general need for robustness and for protection against grit, etc., the drive of steel-works cranes and machine tools does not differ in principle from standard machine-shop practice.

ELECTRIC CRANES AND GANTRIES

Cranes are lifting machines that move an object in three directions at right angles to one another; and in the electric crane each of these movements is carried out by a separate motor and operated by a separate controller, in such a way that all three may be in action at the same time. The problems involved in its design include not only the carrying out of the positive motion, but also the effective stopping of the movement and the lowering of the load at a desired safe speed. Braking thus becomes an important item.

The most common types are jib cranes and girder cranes. For small versions of the latter, the motors are controlled from the floor by means of pendant cords; but for ordinary sizes, the operator travels with the girder in a cab usually suspended from one end. For large varieties, the cab is supported by the carriage itself, which is then termed a "man-trolley." Instead of running along a pair of girders, such a trolley may be arranged to travel on the horizontal members of a gantry, which is supported on two legs having wheels and driving motors, the whole then constituting an "unloading bridge"; or it may travel over a special overhead runway about a yard or warehouse. Other variants, such as the hammer-head crane, as well as the portal crane, semi-portal crane, etc., are in every-day use.

Motors.—The chief features required of crane motors are the ability to overcome heavy starting torques and to accelerate as quickly as possible; and also preferably to lower the load at a convenient speed, the services of an external friction brake being dispensed with whenever possible. The first group of requirements point to the series D.C. or the slip-ring induction motor as being appropriate, but the second indicate the definite superiority of D.C. working; and where a number of cranes are located close together in a district only served by an A.C. supply, it is a frequent practice to employ a converting plant for providing them with direct current. A.C. motors with solenoid brakes are, however, quite a practicable alternative. For such infrequent duty, "crane-rated" windings are the rule, which are generally designed to carry full load for only half to one hour continuously without over-heating.

***Control Gear.**—The control gear may be either of the hand-operated drum or of the automatic contactor type. The former is the standard for the smaller capacities, but the advantages of automatic working often secure the use of contactor gear for small as well as large models. Whichever type is used, the rule is to render the operator's duties as simple and subconscious as possible, in order that he may be able to concentrate almost the whole of his attention upon the movements of the load. What is known as the "sympathetic" arrangement of control levers will be found to very greatly assist towards this end. In this system two of the controllers are so geared together as to be operated by different movements of the same lever; and both levers are so designed that the driver's motions are always in the same direction as those in which he desires the load to travel.

No special comment is needed regarding the control of the two horizontal travels, for which ordinary armature or rotor resistance control is employed. Braking is usually effected by "plugging" or reversing the motor through the whole of the control resistance; and foot brakes may also be used. But the hoisting motor requires quite specialized control when advantage is to be taken of the braking facilities of direct current. Very convenient lowering characteristics are given by what is called "potentiometer" braking, the principle of which is shown in fig. 5. Here the armature of the series motor is reconnected in shunt with a portion of the control resistance, so that it behaves similarly to a shunt motor, acting as a generator (and thus developing a negative torque) when rotating in the same direction as it did as a motor. The full series of connections is indicated in fig. 6, in which an auxiliary solenoid for releasing a friction brake is also shown. The hoisting is carried out in the usual manner, by cutting

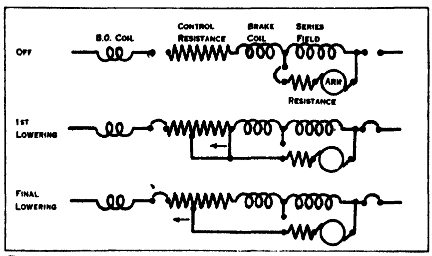

FIG. 8.—DIAGRAM SHOWING CONNECTIONS FOR DYNAMIC AND POTENTIOMETER BRAKING

out the series resistance. In the "off" position, the armature is reconnected in a closed ring with the field and a resistance, giving ordinary "dynamic" braking for bringing about a stop. For the slowest lowering speed, the potentiometer connection is carried out as in the middle diagram, and the speed is increased by progressively cutting the main resistance into the ring circuit and out of circuit with the armature as indicated by the arrows.

For some cranes, such as those used in foundries, very slow speeds and gradual acceleration are needed, and these are ob-

tained by means of diverter control. Series resistance is used, which is cut out in the usual manner; but for extra low speeds, not only is the whole of this left in circuit, but the armature current is further reduced by diverting current from it through a variable resistance shunt. In one controller type the diverting resistance is varied by a drum, which is mechanically interlocked with the larger so that it cannot be moved unless the main drum is in the "off" position, after which the latter can only be advanced to the first or second steps, while the auxiliary drum cannot be moved to the "off" position until the circuit has been ruptured by the main unit.

Contactor controllers carry out the same routine as the manual type, and their circuits do not call for special comment. What are known as "crane protective panels" are employed with any type of gear, and employ a master contactor controlling the current for all the crane motors. An overload relay is provided for each independent circuit, and one also for the common return lead. An excessive current in any can open the contactor, which is reclosed by a special auxiliary switch or contact convenient to the operator. The chief advantage of this type of overload protection is economy of time.

PRINTING MACHINERY AND CALENDERS

A number of industrial operations, of which rotary printing presses form a typical example, involve an accurate regulation of the working speed over a very wide range. Methods of control employing field regulation, resistance in series with the armature, and diverting resistance have already been described; but for the group of functions to be dealt with in this section, additional means are frequently essential.

The inadequacy of series and diverter resistances is chiefly due to their destroying the constant speed characteristic of the shunt motor, and causing serious variability with loading conditions. Field regulation is however available as far as it goes; while the Ward-Leonard system of control is an ideal, though frequently a too expensive, method. Multiple-voltage control is also of assistance. But for many purposes, especially in connection with printing, rubber calendering and paper making, special methods are directed to the great importance of securing a definite and steady slow speed for threading-in; for a sudden spurt immediately the initial static friction is overcome must be rigorously avoided.

For the least exacting requirements, the "inching" starter shown in fig. 2 may be serviceable, since it permits the motor to be inched or "jogged" at slow speed as a preparation to the main run.

More delicate operation is given by a combination of field, series and diverting resistances with two-voltage control; and a scheme for effecting the change-over of voltage together with the other methods is shown in fig. 9. The supply is here assumed to be derived from an ordinary three-wire system at, say, 115/0/–115 volts. There are eight contactors in all, and the scheme of operation would be as follows: Close 1, 2 and 7—thread-in speed; open 2—slow speed; close 3, 4 and 5 in succession—acceleration to half-speed; close 8, then open 3, 4, 5 and 7—transition to full voltage; close 6, 3, 4 and 5 in succession—acceleration to full speed; open 1 and 8, and close 2—stop. This scheme would preferably be combined with field regulation; while all the methods of control need not be included.

Of the special means employed for this class of work, the Holmes-Clatworthy two-motor system will be described for the drive of printing presses, and the Harland interlock scheme for paper machines. The former was developed in 1898, and involves the use of a small worm-geared motor for producing the creeping speeds, and the smooth transference of the drive to a large direct-coupled motor when a given speed has been reached. A magnetically-operated clutch positioned between the small and large machines enables the change-over to be automatic and without shock.

A self-contained control pillar is employed embodying contactors and relays, and a motor-driven distributing switch. The latter cuts resistance into and out of the two motor circuits as required, and opens and closes the circuits for the machines themselves, so that the speed is smoothly and gradually increased as the servo-motor rotates in one direction, and similarly reduced when its rotation is reversed. The gear is operated from any point round the printing press by means of any number of push-button stations. Pressing the "Up" button accelerates the

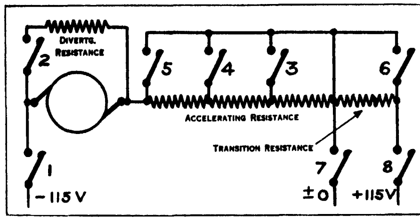

FIG. 9.—DIAGRAM OF TWO VOLTAGE CONTROL SCHEME

speed while it is held down, and the reverse is true of the "Down" button. The "Inch" unit institutes a very slow movement which ceases as soon as the button is released; while the "Lock" button prevents the machine from being started until its own "Free" button is pressed. By all these means the paper is safe-guarded from being torn, and the operators from suffering injury.

The distinguishing feature in connection with paper making is the necessity for maintaining exactly the same relative speeds between all the numerous rollers involved in the process; for great trouble is caused if the paper is either torn or becomes slack. It is nowadays customary to drive the complete machine by a number of electric motors, all of which are supplied with power by a motor-generator set. The speed of the whole process can thus be increased or diminished as required by the field regulation of the generator. The requirement is then to co-ordinate the speeds of the various "section" motors so that none of them can deviate by a fraction of 1% from the predetermined value relatively to the speeds of the other machines.

This co-ordination of speeds may be simply accomplished in the Harland equipment. A master shaft runs transversely to all the motor shafts, and is driven either by a special motor or by that of the "drier" section. One-half of a differential gear, designed on exactly the same principle as that used in a motor car back axle, is spur-geared to this shaft, while the other half is belted to the shaft of the section motor. While the two halves run at the same speed but in opposite directions, the planet wheels and frame do not move; but when movement does occur, resistance is cut into or out of the field circuit, a rheostat having about 100 steps being incorporated in the "differential" case. The most delicate regulation is thereby obtained.

MISCELLANEOUS ELECTRIFICATION

Other plant equipment, the electrification of which deserves brief notice includes the following: lifting magnets, large valves, pumps, compressors, swing bridges.

Lifting Magnets.—The control of a lifting magnet must make provision both for the potential kick that may occur when breaking circuit, and also for the residual magnetism remaining when the exciting current is switched off, which might be sufficient to retain the load. The former is dealt with by connecting a non-inductive "discharge" resistance across the coil just before the supply is cut off; and the latter by means of a momentary reversal of the magnetizing current. A scheme for effecting these steps, and giving two strengths of lifting excitation, is shown in fig. 10. Auxiliary knock-off contactors are used, operated by a drum controller.

Large Valves.—It is becoming the custom to open and close large steam and water valves electrically, to save the delay, danger and discomfort that are involved in manual operation. The motors range from about 1 to 8 h.p., and are series wound for D.C. and squirrel-cage for A.C. The greatest power is re-

quired for unseating the valve, which may be jammed or stuck in place, and the starting torque of the motor is frequently assisted by the provision of "lost motion" to impart a hammer blow. After the valve has begun opening, a series resistance is cut into the D.C. armature circuit to prevent racing. A precaution necessary during the closing operation is to stop the motor in time to pre-

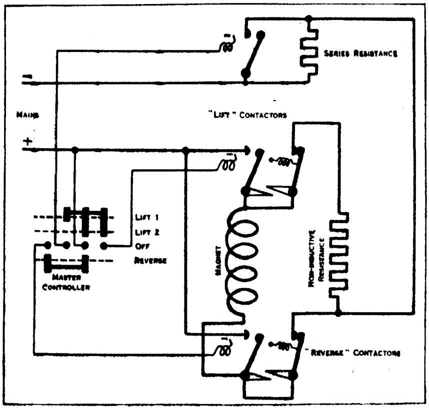

FIG. 10.—DIAGRAM OF CONTROL CONNECTIONS FOR LIFTING MAGNET

vent jamming. This is accomplished by a limit switch and the end is often assisted by a slipping clutch. Several different schemes for D.C. control to suit a manual drum controller and a contactor equipment may be used.

Pumping.—The driving of pumps, both centrifugal and reciprocating, is carried out best by D.C. compound or A.C. squirrel-cage and synchronous motors. It may be made automatic by means of contactor gear, operated by float or pressure relays, and forms an economical load, as it may easily be restricted to off-peak hours. The simplest starting schemes, such as the star-delta, stator resistance, or even direct switching, are in order for A.C. equipment, the latter being obtained by the use of "across-the-line" type of squirrel-cage and synchronous motors. It is only when a long water column has to be accelerated that special care is needed for bringing about a gradual start.

Fans and Air-compressors.—Ventilation is chiefly of importance in connection with mining, for which ventilating practice is tending more and more in the direction of absolutely continuous running, even during holidays. Conditions thus favour the use of synchronous motors, which can be over-excited to enable them to correct the power factor of the electrical installation generally. Since fan duty involves the development of the greatest starting torque just when the rotor is to be pulled into synchronism, an ordinary self-starting synchronous motor is not in order unless a friction clutch is fitted. The latter is not needed with the synchronous induction motor, which starts as a slip-ring machine and has its rotor excited with D.C. when up to speed. It is customary to employ gearing or belting between motor and fan, which can provide for a gradual increase in capacity as the mine develops by means of a change of gear ratio.

For air-compressors, which may be started at light load, the simpler self-starting synchronous motor is well adapted. An appropriate starting scheme would be one that used an auto-transformer which would reduce the initial voltage. The star-point switch is opened during starting and also just before closing the full-voltage switch.

Swing Bridges.—The operation of swing and lift bridges is effected by series D.C. or slip-ring induction motors. The control gear need not be automatic, but must be absolutely certain in its action, and must be capable of moving the very heavy masses involved without any possibility of jerking or jolting. A reliable system of interlocks, brakes and signal lamps is used to prevent all chance of mistakes.

Motors are employed for moving the span, for locking it, and for opening and closing the gates. Locking motors may be of the squirrel-cage type with high resistance rotors, and need only have a 15 min. rating. The main brakes are usually of the shunt-wound solenoid friction pattern, mounted directly on the motor shafts, and emergency brakes are also installed. The limit switches for effecting slow speed preparatory to seating are important components.

Fuller details regarding the subject dealt with above may be obtained from the author's book on *Control Gear and Electrification,* and from other technical productions. (W. WI.)

UNITED STATES

The electrification of America has progressed very rapidly. In 1900 (U.S. Census of Manufactures) there was 11,800,000 h.p. installed in the manufacturing enterprises of which but 4% was electrified. By 1925, the total had reached 35,800,000 horse-power. The American workman in 1900 utilized 2·13 h.p. of which but $\frac{1}{10}$ h.p. was electrical. In 1925, he used 4·27 h.p. of which 3·12 h.p. was electrical. Thus, it is apparent that 31 times as much electrical horse-power was used by each American workman in 1925 as was used in 1900. The economic results produced have justified this progress. The American wage-earner in 1925 produced products valued at $7,500, or nearly three times what he produced in 1900. From 1919, through 1925 there was a 26% increase in the quantity output of American factories, despite the fact that the average number of industrial workers decreased 6·7%.

There has been a very distinct trend by American industry toward the purchase from electric service companies of its power requirements. There has been marked and continued advance in the field of design and application of electrically-actuated apparatus to the many forms of machinery used in the productive industries. The use of the electric motor for individually driving power consuming machinery has been largely responsible for the increased production of products in factories. In the woodworking and textile establishments and in those industries using automatically operated machine tools, such as the automotive industry, where maintenance of the speeds of the cutting or working tools is of prime importance, individual motor drive has proved its value.

During the past few years, the "across-the-line" or "line-start" motor has been developed and has received wide application. Induction motors of this type in sizes up to about 50 h.p. may be connected directly to line voltage through a simple magnetically operated switch without exceeding N.E.L.A. specifications for starting current. The use of this motor has greatly simplified the control gear required. Synchronous motors of this type have also been developed and permit the use of simple control for heavy starting duty. Considerable attention has been given to the development and application of fan-cooled motors both for A.C. and D.C. and of fully enclosed motors designed for use in places where they are subjected to all kinds of destructive substance.

There is a decided increase in the application of high-speed motors. Squirrel cage motors operating at speeds up to 32,400 r.p.m. have been applied to regular production equipment in the ball-bearing industry through the use of frequency changers equipped with 540 cycle generators. In the woodworking industry 120 and 180 cycle motors are being used. The large majority of electrified power consuming equipment in industry is operated by A.C. motors. The predominant use of A.C. has resulted from the simplicity and ruggedness of the squirrel cage motor and its suitability for constant-speed applications. D.C. motors are used where the advantages of variable speed justify the increased cost of operation. The advance in A.C. motor design, however, has placed at the disposal of industry sufficient satisfactory types that all but very special applications may be served with A.C. motors.

Large factories usually utilize both types of current. Equip-

ment operated at constant speeds are equipped with A.C. motors and D.C. motors are used where variable speed is required. The tendency to equip main roll drives in iron and steel mills with electric drive was continued. These installations utilize mainly D.C. motors of slow speed driven from individual fly-wheel type motor-generators. Some progress has been made in the use of synchronous motors for main roll drives. D.C. mill-type motors have been placed on the market by one American manufacturer. In the rubber industry a synchronous motor having a sufficiently high starting torque to start heavy loads is now available for driving grinding mills, rolls and mixers. This motor operates as an induction motor when it drops out of synchronism and then automatically drops back into step.

A comparatively recent and valuable development has been the application of electric motor drive in the petroleum industry for driving wells in the fields and large pumps in main line pumping stations. Electrically driven drilling rigs have replaced with complete satisfaction and economy drilling equipment driven by steam and internal-combustion engines. Improvements in the design of mine-type locomotives have resulted in a continuation of the trend toward complete electrification in this industry. Depression in the industry has retarded the electrification programme but in spite of this each year sees more steam-actuated equipment replaced by electric drives. Perhaps the most fertile field for further electrification of our industrial establishments lies in the application of electricity to heating processes. Considerable progress has already been made in this direction. There is every reason to believe that some day the horse-power rating of electric heating and melting equipment in American industry will exceed the total horse-power in motors.

The brass industry for several years has made use of large induction and arc type furnaces for melting copper alloys in the comparatively few large wrought-brass mills. The development of small units (250 and 1,000 lb. capacity), practically all of which are of the single-phase type, have made possible electric melting in the smaller cast-brass establishments. Up to the year 1926 less than 15% of the brass melted in America was melted in electric furnaces. In the steel industry, the three-phase arc furnace produces such a high quality of product that "electric steel" has now become virtually a trade-mark. A few installations of this type of furnace have been made for the melting of cast iron and it is expected that this will find larger application. A high-frequency or coreless-type induction furnace has been developed for the melting of high-grade alloy steels. Each of these units consists of a motor-generator set with a single-phase high frequency generator and high-frequency capacitor units. The advantages of the electric furnace in producing very high temperatures, in allowing exact temperature adjustment and in providing the possibility of controlling the conditions of operation has established it in the large commercial field where these refinements are necessary. Some of the products in this field are artificial graphite, silicon carbide, artificial emery, metallic silicon, fused quartz, fused silica, fused silico-glass, bisulphide of carbon, zinc, phosphorus, calcium carbide, ferro-alloys and other alloys, and steel. Experimentally the electric furnace has been used to produce modifications of carbon, many metals and a great variety of other products.

When steel is made into forging, cold rolled into sheets and strips or drawn into wire, the working of the metal imparts a certain amount of hardness which must be removed by annealing, before subjecting the material to subsequent operations. Thus forgings must be softened for machining and sheets must be put in suitable condition for drawing and forming operations. Wire is annealed after each draw to reduce wear of dies and increase ductility of the metal. There is then a final anneal or heat treatment to make the wire suitable for commercial use. Until about 1922 commercial annealing was carried on in fuel-fired furnaces using coal, coke, oil or gas, and these methods are still in quite general use. The tendency at present, where maximum quality and uniformity of product are desired, is to give consideration to the electric furnace for these operations. The actual cost of the electric energy used is, in many instances, higher than the bare cost of fuel would be, but this is frequently justified by the results secured. A properly designed electric furnace operates with a very uniform distribution of heat and at no time is the temperature of the heat source much above the annealing temperature. This means that the metal is heated through to just the right degree and will have the uniform grain structure which characterizes a perfect anneal. The furnace temperature is controlled automatically and is maintained more closely and accurately than is possible with the average fuel-heated furnace and this is accomplished with a minimum of attendant labour. Usually the annealing process may be carried out overnight which permits the use of off-peak power purchased at minimum cost and often the same furnace is used during the day for other heat-treating operations.

Electricity has been applied successfully and economically to such low-temperature industrial processes, as japanning and enamelling, core baking, glue melting, firing of glassware and sherardizing. Electric furnaces operating at temperatures in excess of 1,000° F are being used for annealing, carbonizing, hardening and for vitreous enamelling. Electric heating removes all the difficulties that result from fuel combustion taking place where the heat is applied. The atmosphere in which the heating is done can be made the most suitable for the treatment given. The temperature also can be controlled exactly in all parts of the oven by the proper number and placing of the heating elements. These are the reasons for the small number of articles rejected by inspectors after electric heat treatment and consequently for the saving obtained over other processes where combustion is present and the temperature not so exactly controlled. Electric heating has also often been found to produce articles of higher quality than are produced by other methods. This is also a reason for its quite general application. The small number of rejects and the improved quality of the article are important factors in determining the cost of electric heat for various treatments in comparison with other methods.

Electric welding both by the electric arc and the resistance method is continuously finding more application and much progress has been made in the use of the automatic electric welding machine. On articles of simple shapes and in quantity production these machines are doing work cheaply and very well. The personal equation of the operator is removed and all the elements are controlled so as to produce the best weld. Semi-automatic welding machines are also finding considerable use. Here the feed of the electrode and the arc length are automatically controlled but the travel of the arc is under hand control so that the machines can be used on articles of a great variety of shapes. Welding has been used on structural steel parts in the place of rivets. If arc welding should prove, after more experimentation and experience, the best method for this work, the automatic machine will find an enormous field of application in the fabricating shop.

One of the recent forms of electric welding development has been that known as the atomic hydrogen weld. In this process an arc is maintained between two tungsten electrodes. A stream of hydrogen emerging from the electrode holder envelops the electrodes and thus prevents their oxidation and at the same time acts as the heat carrier. The hydrogen molecules are dissociated by the intense heat of the arc into the atomic state. Upon striking the relatively cool surfaces being welded, these atoms re-combine with the liberation of intense heat. The intensity of the heat and the complete shielding of the fused metal with hydrogen preventing contamination by the oxygen and nitrogen, results in the formation of an unusually sound, smooth and ductile weld. It makes possible the welding of many alloys that have not readily lent themselves to welding by other processes. Atomic hydrogen welding has found its principal application in the welding of light sections where appearance and ductility are of first consideration, and in the welding of special alloys.

The picture of electrification progress would be incomplete without some reference to the recent trend toward railroad electrification. (Details of this development are to be found in the article RAILWAYS.) Adequate lighting is to-day playing a very important part in our manufacturing processes and a description of this is

given in the article on LIGHTING. It is impossible to treat adequately the development of the electrification of industry under any one heading and the following articles should be referred to in addition to those cited above: ELECTRICAL POWER GENERATION; ELECTRICAL POWER TRANSMISSION; ELECTRICAL GENERATOR; MOTOR, ELECTRIC; ELECTRIC TRACTION; ELECTRICITY SUPPLY, COMMERCIAL AND TECHNICAL ASPECTS; ELECTRICAL POWER IN AGRICULTURE; HOUSEHOLD APPLIANCES; IRON AND STEEL; ALLOYS; METALLURGICAL FURNACES; POWER TRANSMISSION, MECHANICAL; MACHINE TOOLS; METALLURGY; PETROLEUM; and various industrial processes under their own heading.

(H. C. TH.)

ELECTROCHEMISTRY, that branch of *physical chemistry* (*q.v.*) which is concerned with the relation between electricity and chemical change. Under ordinary conditions, the occurrence of a chemical reaction is accompanied by the liberation or absorption of heat and not of any other form of energy, but there are many spontaneously occurring chemical reactions which, when allowed to proceed under special circumstances, liberate electrical energy, an electric current being generated. Conversely, the energy of an electric current can be utilized to bring about many chemical reactions which do not occur spontaneously. A process of the former type involves the direct conversion of the *chemical energy,* which is causing a reaction, into *electrical energy,* and an apparatus whereby such a process is brought about constitutes a *primary cell.* On the other hand, in processes of the latter kind, electrical energy is directly converted into chemical energy, which is stored up in the products of the reaction: such a process is one of *electrolysis*—an *electrolytic process.* In virtue of their chemical energy, the products of an electrolytic process have a tendency to react spontaneously with one another, reproducing the substances that were consumed during the electrolysis, so that, if this reaction is allowed to occur under such conditions that a primary cell is formed, a large proportion of the electrical energy used in the electrolysis may be regenerated. This possibility is made use of in *secondary cells*—also known as *accumulators* or *storage batteries.* The charging of an accumulator is a process of electrolysis, a definite chemical change being produced by the electric current passed through the cell. In discharging the cell, the reverse chemical change occurs spontaneously, the accumulator acting now as a primary cell furnishing an electric current. The "storage" of electrical energy in a secondary cell thus involves its conversion into chemical energy, which can, however, be reconverted into electrical energy when desired.

In addition to these purely electrochemical processes, it is customary to include also under the heading of electrochemistry those processes in which the energy of an electric current is first converted into heat, which then serves to bring about a chemical reaction which would not occur spontaneously at ordinary temperatures. These *electrothermal chemical processes* thus represent the indirect conversion of electrical energy into chemical energy through the medium of heat, and an apparatus in which they can occur is an *electric furnace.* Still more indirect processes, however, would not be regarded as electrochemical. Thus, in generating electricity on the large scale, the electrical energy is actually derived from the chemical energy of fuels such as coal, coke or oil, but the operation is not claimed as an electrochemical one, since the chemical energy is first converted into heat by combustion of the fuel, heat is then converted into mechanical energy by some form of heat engine, and finally mechanical energy is transformed into electrical energy by means of the dynamo. Although in this very indirect process only a fraction of the available chemical energy of the fuel can actually be obtained in the electrical form—mainly owing to the low efficiency of the heat engine stage—yet no known type of primary cell can be expected to compete with it, since in the operation of such cells relatively expensive material, usually zinc, is consumed continuously. Attempts to devise an efficient primary cell, capable of producing electrical energy directly from the chemical energy of ordinary fuels, have frequently been made, but although many difficulties have been overcome, none of the *fuel cells* yet designed have been successful on the commercial scale.

Finally, the *passage of electricity through gases* generally causes chemical changes, and this subject forms a separate branch of electrochemistry. When the current passes in the form of the so-called "silent" discharge, the chemical effects must be attributed to the direct action of the electrical energy supplied, but such a process is not an electrolysis, in the usual sense of the term. In cases where the discharge takes the form of an electric arc, much heat is liberated at very high temperatures and the chemical changes produced are the result of combined electrical and thermal conditions, *i.e.,* such processes are partly electrothermal in character.

General Principles.—Substances which are reasonably good conductors of electricity may be divided into two groups, the *metallic* or *electronic conductors* and the *electrolytic conductors.* The metals and a few substances such as graphite, manganese dioxide and lead sulphide exhibit metallic conductivity: the passage of an electric current through them produces heating and magnetic effects but no chemical changes. Electrolytic conductors or *electrolytes* comprise most acids, bases and salts, either in the molten condition or in the state of solution in water or other liquids. Plates or rods composed of a suitable metallic conductor dipping into the fluid electrolyte are employed to conduct the current into and out of the liquid, *i.e.,* to act as *electrodes.* When a current is passed through an electrolyte between suitable electrodes, not only are heating and magnetic effects produced, but also definite chemical changes occur at or in the neighbourhood of the electrodes, the process being one of electrolysis. At the negative electrode or *cathode,* the chemical change may be either the deposition of a metal, or the liberation of hydrogen and formation of a basic substance, or some other *chemical reduction* process; whereas at the positive electrode or *anode* it may be either the dissolution of the anode itself, the liberation of a nonmetal, the production of oxygen and an acidic substance, or some other *chemical oxidation* process. In some cases, these primary products of electrolysis then react with the electrolyte or with the material of which the electrodes are composed, yielding secondary products. It was shown by Faraday that the weight in grams of any of the primary products of an electrolysis liberated by Q coulombs of electricity is equal to $Qz/96{,}500$, where z is the *chemical equivalent* of that substance: hence to produce a gram-equivalent of any of the products of an electrolysis requires 96,500 coulombs of electricity.

An electrolyte, prepared either by melting a suitable substance or dissolving it in water or other liquid, owes its characteristic properties to the presence in it of electrically charged atoms or groups of atoms produced by the spontaneous splitting up or dissociation of the molecules of the substance when it is melted or dissolved. In the so-called *strong electrolytes,* most of the molecules of the original substance, or probably all of them, have undergone this process of *electrolytic dissociation* into charged particles or *ions* (*see* SOLUTION). When a potential difference is established between electrodes dipping into an electrolyte, positively charged ions move towards the negative electrode and ions bearing a negative charge towards the positive electrode, the electric current being carried through the electrolyte by this migration of the ions (*see* CONDUCTION IN LIQUIDS). When an ion actually reaches the electrode of opposite polarity, the neutralization of its charge converts it into an ordinary neutral atom or group of atoms and it is this *discharge of ions* which gives rise to the chemical changes at the electrodes. Thus, copper sulphate, $CuSO_4$, when dissolved in water forms an electrolyte, since it dissociates under these conditions into positively charged copper ions, Cu^{++}, and negatively charged sulphate ions, $(SO_4)^{--}$. When an electric current is passed through the solution by way of platinum electrodes, the copper ions move towards the cathode and on reaching it are discharged, giving metallic copper which is deposited on this electrode. At the anode the (SO_4) groups produced by the discharge of sulphate ions are unstable and react with water, producing oxygen which is evolved as bubbles of gas and sulphuric acid which accumulates in the solution around the anode. The total chemical change at the two electrodes may therefore be represented by the equation:

$$2CuSO_4+2H_2O+\text{electrical energy}\rightarrow 2Cu+2H_2SO_4+O_2.$$

A simpler case is that of an aqueous solution of copper chloride, $CuCl_2$, in which the ions are Cu^{++} and Cl^-, the latter yielding only chlorine gas when discharged at the anode. The equation for the complete electrolysis is $CuCl_2$+electrical energy→$Cu+Cl_2$ (*see* ELECTROLYSIS).

The quantity of electricity required to produce, say, 1 gram of copper by the electrolysis of either of the above solutions is 96,500/31·78=3,036 coulombs, since 31·78 is the chemical equivalent of copper in salts of this type. But the quantity of electrical energy needed for this purpose is given by the product of the quantity of electricity and the voltage which was applied across the electrodes during the electrolysis. If the current strength through a given electrolyte is to be I amperes, then the *applied voltage*, E_I, is given by: $E_I=E_0+IR+\pi$, where IR is the voltage used in overcoming the resistance, R ohms, of the column of electrolyte between the electrodes; and π denotes the *polarization* of the cell, a quantity which depends on the nature and concentration of the electrolyte, the nature of the electrodes, and the *current density, i.e.*, the ratio of I to the surface area of the electrodes in contact with the electrolyte. If the current density is large, π may be considerable, but as I is decreased π approaches zero. The minimum value of E_I which is approached as I is diminished is E_0, the *decomposition voltage* of the given electrolyte with the given electrodes. This represents the voltage which must be exceeded if electrolysis is to occur at all. For an aqueous solution of copper chloride of *normal* concentration, $E_0=1{\cdot}06$ volt. The electrical energy needed to liberate 1 gram of copper from this solution under given conditions is $3{,}036\times E$ joules, and the minimum value of this quantity under any conditions is $3{,}036\times E_0=3{,}036\times 1{\cdot}06=3{,}220$ joules. This value represents also the decrease of chemical energy when 1 gram of copper and the equivalent amount of chlorine (1·115 grams) are converted into copper chloride solution. In practice rather more electrical energy is always needed, since E_I is necessarily somewhat greater than E_0. This additional energy is used in overcoming resistance and polarization effects and is thereby converted into heat.

In virtue of their chemical energy, the products of an electrolysis tend to react with one another if allowed to come into contact. Thus, copper and chlorine interact readily, forming copper chloride and liberating a considerable quantity of heat—the *heat of reaction*. By setting up a primary cell, however, in which a copper electrode and a chlorine electrode dip into a solution of copper chloride, this same reaction can be caused to occur so as to yield electrical energy. For this purpose the copper electrode may consist of a plate of the metal, but, in order that chlorine may function as an electrode, a conductor of some material that is not attacked by chlorine must be used to act as an intermediary between the gas and the solution. A plate of platinized platinum or a rod of porous carbon kept saturated with the gas will act as a chlorine electrode. If the copper chloride solution is of normal concentration, the chlorine electrode will be found to assume a potential which is 1·06 volt more positive than the copper electrode, *i.e.*, the *electromotive force* of the cell=1·06= E_0, the decomposition voltage of the electrolyte. If now the two electrodes be connected by means of a wire outside the cell, a current will pass through the circuit formed by the electrolyte, the electrodes and the external wire. Whenever the cell is allowed to deliver a current through an external circuit, chemical changes occur at the electrodes, viz., copper dissolves from one electrode forming Cu^{++} ions and chlorine goes into solution as Cl^- ions at the other, so that, although the copper and chlorine do not actually come into contact, the total chemical reaction is

$$Cu+Cl_2\rightarrow CuCl_2+\text{electrical energy},$$

which is exactly the reverse of that occurring in the electrolysis of copper chloride solution.

For every gram of copper which dissolves during the action of the cell, 3,036 coulombs of electricity are obtained. The amount of electrical energy obtained, however, is $3{,}036\times E'_I$, where E'_I is the actual voltage or potential difference between the electrodes of the cell, when it is furnishing a current of I amperes. For a primary cell, $E'_I=E_0-IR-\pi'$, where these symbols have the same significance as above, π' being the polarization of the cell under the given conditions. If I is made very small by using an external circuit of very high resistance, π' approaches zero, E'_I approaches E_0, and the electrical energy obtainable approximates to $3{,}036\times E_0=3{,}036\times 1{\cdot}06=3{,}220$ joules per gram of copper dissolved. This quantity represents the maximum amount of electrical energy obtainable from the given chemical change and is a measure of the chemical energy which is causing the reaction to proceed. It should be noticed that the heat evolved when a reaction occurs under ordinary conditions is not generally equal to the chemical energy. Hence, in general, some heat is evolved or absorbed even when a primary cell is operated so that it is furnishing the maximum amount of electrical energy corresponding to the chemical change. Thus, a lead accumulator absorbs heat from its surroundings when it is being discharged.

Returning for a moment to the question of electrolysis, it must be pointed out that, if a copper chloride solution is electrolyzed using copper electrodes, copper is deposited on the cathode, but under these conditions copper is also dissolved from the anode at an equal rate, so that no chemical change occurs in the cell as a whole. Copper is merely transferred from the anode to the cathode and the decomposition voltage is zero. Processes of this kind are largely employed in refining metals. Using anodes of the crude metal, conditions are arranged so that impurities in these anodes do not deposit with the metal on the cathode during electrolysis. The small voltage required is merely that needed to overcome resistance and polarisation effects.

Apart from electrolytic conductivity, which has been considered above, and electronic conductivity, which is ascribed to the movements of free electrons through a metallic conductor, the *conductivity of gases* should also be mentioned. Under ordinary conditions, gases are practically insulators, the very small electrical conductivity which they do possess being attributed to the accidental presence of a few *gaseous ions* (charged atoms or molecules). When a high potential difference is established between electrodes in a gas, these ions move towards the electrode of opposite polarity with considerable velocities, so that if they collide with neutral molecules of the gas, they may be able to split up the latter into ions. With a sufficiently high voltage, this *ionization by collision* becomes important, and, as more and more ions are formed, the conductivity of the gas increases. But ions carrying charges of opposite sign may also collide with one another and form neutral molecules again. With a given voltage the current through the gas will attain a steady value when the rate of formation of ions is equal to their rate of recombination. With oxygen gas, some oxygen molecules, O_2, may be ionized into O^+ and O^-, whereas others may yield O_2^+ and a free electron. If now the ions O^- and O_2^+ collide, a molecule of ozone, O_3, may be formed. Chemical changes due to the passage of electricity through other gases arise in a similar way.

The *heating effects*, which are produced when large electric currents are driven by means of high voltages through metallic conductors or gases, are utilized in electrothermal chemical processes. Alternating currents can generally be used for this purpose.

Industrial Applications.—Electrolytic processes are employed commercially in the extraction of metals such as aluminium, magnesium, sodium, zinc and nickel from their ores; in refining metals such as gold, silver, copper, lead and tin; in electroplating with various metals and alloys; and in producing substances such as caustic soda, hypochlorites, chlorates, hydrogen and oxygen, the so-called "per-salts," etc. Electrothermal chemical processes have been applied to the smelting of ores of metals such as iron and zinc; to the production of ferro-alloys; to the refining of steel; and to the manufacture of substances such as calcium carbide, carborundum and phosphorus. The preparation of ozone and the production of nitric oxide from air (*see* NITROGEN, FIXATION OF) are processes depending on the passage of electricity through gases. Primary cells of various types, including "dry cells," are widely used for furnishing small, intermittent supplies of electricity, whilst the lead accumulator and the iron-nickel accumulator are the chief types of secondary cell employed technically

for the storage of limited quantities of electricity. For information on particular processes the reader is referred to articles on special branches of the subject, *e.g.*, BATTERIES, ELECTRIC; ELECTROMETALLURGY; ELECTRICITY, CONDUCTION OF; ELECTROTHERMICS; ELECTROPLATING; ZINC; CARBORUNDUM; OZONE; etc., which will be found under their respective titles.

Pring, *The Electric Furnace* (1921); F. Foerster, *Elektrochemie wässeriger Lösungen* (Leipzig, 1923). (H. J. T. E.)

ELECTROCUTION, the popular name, invented in America, for the infliction of the death penalty on criminals by passing through the body of the condemned a current of electricity sufficient to cause death. The method was first adopted by the State of New York, a law making this method obligatory having been passed and approved by the governor on June 4, 1888. The first criminal to be executed by this method was William Kemmler, on Aug. 6, 1890, at Auburn prison. The validity of the New York law had previously been attacked in regard to this case, as providing "cruel and unusual punishment" in violation of the Constitution; but it was sustained in the State courts and finally in the Federal courts (*Re Kemmler*, 1889, 136 U.S. 436). This method of inflicting the death penalty has now (1928) been adopted in 23 States.

The death dealing apparatus consists of a stationary engine, an alternating dynamo capable of generating a current at a pressure of 2,000 volts, a "death-chair" with adjustable head-rest, binding straps and adjustable electrodes. The voltmeter, ammeter and switch-board controlling the current are located in the execution-room; the dynamo-room is communicated with by electric signals. When everything is in readiness the criminal is brought in and seats himself in the death-chair. His head, chest, arms and legs are secured by broad straps; one electrode thoroughly moistened with salt-solution is affixed to the head, and another to the calf of one leg, both electrodes being moulded so as to secure good contact. The application of the current is usually as follows: the contact is made with a high voltage (1,800–2,000 volts) for three or four seconds, reduced to 500 volts until nearly a minute has elapsed; raised to high voltage for a second or two, again reduced to a low voltage until one minute has elapsed, when it is again raised to the high voltage for a few seconds and the contact broken. A second or even a third brief contact is sometimes made, partly as a precautionary measure, but rather the more completely to abolish reflexes in the dead body. The time consumed by the strapping-in process is usually about 45 seconds, and the first contact is made about 70 seconds after the criminal has entered the death-chamber.

When properly performed the effect of the operation is believed to be painless and instantaneous death. Scientific opinion is divided on this point but there can be little doubt that circulation and respiration cease with the first contact; that consciousness is blotted out instantly and that the prolonged application of the current ensures permanent derangement of the vital functions beyond recovery. To make assurance doubly sure, the law provides for an autopsy to be performed immediately after the execution.

ELECTROLIER, a fixture, usually suspended from the ceiling, for holding electric lamps. The word is analogous to chandelier, from which it was formed, but is used to differentiate the electric from the candle sources of light (*see* CHANDELIER).

ELECTROLYSIS (ĕl-ĕk-trŏl'ĭ-sĭs). The passage of an electric current through a substance, accompanied by definite chemical changes which are independent of the heating effects of the current, is known as electrolysis (formed from Gr. λύειν, to loosen), and the substance is called an electrolyte. An example of this is a solution of a salt such as copper sulphate in water, through which an electric current is passed between copper plates, when the following phenomena are observed: (1) the bulk of the solution is unaltered, except that its temperature may be raised owing to the usual heating effect, which is proportional to the square of the strength of the current; (2) the copper plate by which the current is said to enter the solution, *i.e.*, the plate attached to the so-called positive terminal of the battery or other source of current dissolves away, the copper going into solution as copper sulphate; (3) copper is deposited on the surface of the other plate, being obtained from the solution; (4) changes in concentration are produced in the neighbourhood of the two plates or electrodes. In this case the solution becomes stronger near the anode or electrode at which the current enters, and weaker near the cathode or electrode at which it leaves the solution. If instead of copper electrodes plates of platinum are employed, copper is still deposited on the cathode, but instead of the anode dissolving, free sulphuric acid appears in the neighbouring solution, and oxygen gas is evolved at the surface of the platinum plate. With other electrolytes similar phenomena appear, though the primary chemical changes may be masked by secondary actions. Thus, with a dilute solution of sulphuric acid and platinum electrodes, hydrogen gas is evolved at the cathode, while, as the result of a secondary action on the anode, sulphuric acid is there re-formed and oxygen gas evolved. Again, with the solution of a salt such as sodium chloride, the sodium, which is primarily liberated at the cathode, decomposes the water and evolves hydrogen, while the chlorine may be evolved as such, may dissolve the anode or may liberate oxygen from the water, according to the nature of the plate and the concentration of the solution.

The distinction between electrons associated with gases and with liquids is that, in gases the electrons sometimes travel alone, but in liquids they are always attached to matter and their motion involves the movement of chemical atoms or groups of atoms. An atom with an extra corpuscle is a univalent negative ion, an atom with one corpuscle detached is a univalent positive ion. In metals the electrons can slip from one atom to the next, since a current can pass without chemical action. When a current passes from an electrolyte to a metal, the electron must be detached from the atom it was accompanying and chemical action be manifested at the electrode.

Alessandro Volta of Pavia discovered the electric battery in the year 1800, and thus placed the means of maintaining a steady electric current in the hands of investigators who, before that date, had been restricted to the study of the isolated electric charges given by frictional electric machines. Volta's cell consists essentially of two plates of different metals, such as zinc and copper, connected by an electrolyte such as a solution of salt or acid. Immediately on its discovery intense interest was aroused in the new invention, and the chemical effects of electric currents were speedily detected. W. Nicholson and Sir A. Carlisle found that hydrogen and oxygen were evolved at the surfaces of gold and platinum wires connected with the terminals of a battery and dipped in water. The volume of the hydrogen was about double that of the oxygen, and, since this is the ratio in which these elements are combined in water, it was concluded that the process consisted essentially in the decomposition of water. These observers also noticed that a similar kind of chemical action went on in the battery itself. Soon afterwards William Cruickshank decomposed the magnesium, sodium and ammonium chlorides, and precipitated silver and copper from their solutions, an achievement which led to the process of electroplating. He also found that the liquid round the anode became acid, and that round the cathode alkaline. In 1804 W. Hisinger and J. J. Berzelius stated that neutral salt solutions could be decomposed by electricity, the acid appearing at one pole and the metal at the other. In 1806 Sir Humphry Davy proved that the formation of acid and alkali when water was electrolysed was due to saline impurities in the water. He had shown previously that decomposi-

FIG. 1.—DIAGRAM SHOWING THAT THE RATIO OF SALT LOST AT THE ANODE AND THE CATHODE IS EQUAL TO THE RATIO OF THE VELOCITIES OF THE CATION AND THE ANION (WHITE CIRCLES)

In the bottom figure, the anion travels twice as fast as the cation, and the amount of salt lost at the anode is correspondingly less

tion of water could be effected even if the two poles were placed in separate vessels connected by moistened threads. In 1807 he decomposed potash and soda, previously considered to be elements, by passing the current from a powerful battery through the moistened solids, and thus isolated the metals potassium and sodium.

Faraday's Laws.—The first exact quantitative study of electrolytic phenomena was made about 1830 by Michael Faraday (*Experimental Researches*, 1833), who examined the relation between the flow of electricity round the circuit and the amount of chemical decomposition. He found that, for the same current, the amount of chemical action was independent of the size of the electrodes and proportional to the time that the current flowed. The results of all these experiments may be summed up in the statement that the amount of chemical action is proportional to the quantity of electricity which passes through the cell.

Faraday's next step was to pass the same current through different electrolytes in series. He found that the amounts of the substances liberated in each cell were proportional to the chemical equivalent weights of those substances. Thus, if the current be passed through dilute sulphuric acid between hydrogen electrodes, and through a solution of copper sulphate, it will be found that the mass of hydrogen evolved in the first cell is to the mass of copper deposited in the second as 1 is to 31·8. Now this ratio is the same as that which gives the relative chemical equivalents of hydrogen and copper, for 1 gm. of hydrogen and 31·8 gm. of copper unite chemically with the same weight of any acid radical such as chlorine or the sulphuric group, SO_4. Faraday examined also the electrolysis of certain fused salts such as lead chloride and silver chloride. Similar relations were found to hold and the amounts of chemical change to be the same for the same electric transfer as in the case of solutions. We may sum up the chief results of Faraday's work in the statements known as Faraday's laws:—The mass of substance liberated from an electrolyte by the passage of a current is proportional (1) to the total quantity of electricity which passes through the electrolyte, and (2) to the chemical equivalent weight of the substance liberated.

Since Faraday's time his laws have been confirmed by modern research, and in favourable cases have been shown to hold good with an accuracy of at least one part in a thousand. The principal object of this more recent research has been the determination of the quantitative amount of chemical change associated with the passage for a given time of a current of strength known in electromagnetic units. The mean result of the best determinations shows that when a current of 1 ampere is passed for 1 second, a mass of silver is deposited equal to 0·001118 gm. So accurate and convenient is this determination that it is now used conversely as a practical definition of the ampere, which (though defined theoretically in terms of magnetic force) is defined practically as the current which in one second deposits 1·118 mg. of silver. If, as is now usual, we take the equivalent weight of oxygen as our standard and call it 16, the equivalent weight of silver is 107·88, that of hydrogen being 1·008, and its electrochemical equivalent $1{\cdot}036 \times 10^{-5}$. The electrochemical equivalent of any other substance may be found by multiplying its chemical equivalent by $1{\cdot}036g \times 10^{-5}$. If, instead of the ampere, we take the c.g.s. electromagnetic unit of current, this number becomes $1{\cdot}036 \times 10^{-4}$.

It was pointed out by Helmholtz in 1881 that Faraday's law forms one of the most important reasons for assuming that electricity has an atomistic structure since it must be assumed that every valence bond in an atom or radical involves a definite quantity of electricity, just as in the formation of a chemical compound several atoms or radicals are able to unite with one another. Further according to Helmholtz if the assumption is made that simple substances are composed of atoms, the conclusion cannot be avoided that electricity, positive as well as negative, decomposes into definite elementary particles which behave as electrical atoms. If Avogadro's number N (the number of molecules in a gram-molecule) is known, the size of the elementary charge of electricity e_0, is given in accordance with Faraday's law by the relation $e_0 = \frac{96{,}500}{N}$ coulombs (or ampere seconds) $= \frac{9{,}650}{N}$ absolute electromagnetic units (e.m.u) $= \frac{28{\cdot}95 \times 10^{13}}{N}$ absolute electrostatic units (e.s.u.).

Chemical Nature of the Ions.—A study of the products of decomposition does not necessarily lead directly to a knowledge of the ions actually employed in carrying the current through the electrolyte. Since the electric forces are active throughout the whole solution, all the ions must come under its influence and therefore move, but their separation from the electrodes is determined by the electromotive force needed to liberate them. Thus, as long as every ion of the solution is present in the layer of liquid next the electrode, the one which responds to the least electromotive force will alone be set free. When the amount of this ion in the surface layer becomes too small to carry all the current across the junction, other ions must also be used, and either they or their secondary products will appear also at the electrode. In aqueous solutions, for instance, a few hydrogen (H) and hydroxyl (OH) ions derived from the water are always present, and will be liberated if the other ions require a higher decomposition voltage and the current be kept so small that hydrogen and hydroxyl ions can be formed fast enough to carry all the current across the junction between solution and electrode.

The issue is also obscured in another way. When the ions are set free at the electrodes, they may unite with the substance of the electrode or with some constituent of the solution to form secondary products. Thus the hydroxyl mentioned above decomposes into water and oxygen, and the chlorine produced by the electrolysis of a chloride may attack the metal of the anode.

Early Theories of Electrolysis.—The obvious phenomena to be explained by any theory of electrolysis are the liberation of the products of chemical decomposition at the two electrodes while the intervening liquid is unaltered. To explain these facts T. Grotthus (1785–1822) in 1806 put forward an hypothesis which supposed that the opposite chemical constituents of an electrolyte interchanged partners all along the line between the electrodes when a current passed. Thus, if the molecule of a substance in solution is represented by AB, Grotthus considered a chain of AB molecules to exist from one electrode to the other. Under the influence of an applied electric force, he imagined that the B part of the first molecule was liberated at the anode, and that the A part thus isolated united with the B part of the second molecule, which, in its turn, passed on its A to the B of the third molecule. In this manner, the B part of the last molecule of the chain was seized by the A of the last molecule but one, and the A part of the last molecule liberated at the surface of the cathode. Chemical phenomena throw further light on this question. If two solutions containing the salts AB and CD be mixed, double decomposition is found to occur, the salts AD and CB being formed till a certain part of the first pair of substances is transformed into an equivalent amount of the second pair. A freedom of interchange is thus indicated between the opposite parts of the molecules of salts in solution, and it follows reasonably that with the solution of a single salt, say sodium chloride, continual interchanges go on between the sodium and chlorine parts of the different molecules.

These views were applied to the theory of electrolysis by R. J. E. Clausius. He pointed out that it followed that the electric forces did not cause the interchanges between the opposite parts of the dissolved molecules but only controlled their direction. Interchanges must be supposed to go on whether a current passes or not, the function of the electric forces in electrolysis being merely to determine in what direction the parts of the molecules shall work their way through the liquid and to effect actual separation of these parts (or their secondary products) at the electrodes. This conclusion is supported also by the evidence supplied by the phenomena of electrolytic conduction. (*See* ELECTRICITY, CONDUCTION OF: *In Liquids*.) If we eliminate the reverse electromotive forces of polarization at the two electrodes, the conduction of electricity through electrolytes is found to conform to Ohm's law; that is, once the polarization is overcome, the current is proportional to the electromotive force applied to the bulk of the liquid. Hence there can be no reverse forces of polarization inside the liquid itself, such forces being confined to the surface

of the electrodes. No work is done in separating the parts of the molecules from each other. This result again indicates that the parts of the molecules are effectively separate from each other, the function of the electric forces being merely directive.

Migration of the Ions.—The opposite parts of an electrolyte which work their way through the liquid under the action of the electric forces were named by Faraday the ions—the travellers. The changes of concentration which occur in the solution near the two electrodes were referred by W. Hittorf (1853) to the unequal speeds with which he supposed the two opposite ions to travel. It is clear that, when two opposite streams of ions move past each other, equivalent quantities are liberated at the two ends of the system. If the ions move at equal rates, the salt which is decomposed to supply the ions liberated must be taken equally from the neighbourhood of the two electrodes. But if one ion, say the anion, travels faster through the liquid than the other, the end of the solution from which it comes will be more exhausted of salt than the end towards which it goes. If we assume that no other cause is at work, it is easy to prove that, with non-dissolvable electrodes, the ratio of salt lost at the anode to the salt lost at the cathode must be equal to the ratio of the velocity of the cation to the velocity of the anion. This result may be illustrated by fig. 1.

The black circles represent one ion and the white circles the other. If the black ions move twice as fast as the white ones, their distribution after the passage of a current will be represented by the lower part of the figure. Here the middle part of the solution is unaltered and the number of ions liberated is the same at either end, but the amount of salt left at one end is less than that at the other. On the right, towards which the faster ion travels, five molecules of salt are left, being a loss of two from the original seven. On the left, towards which the slower ion moves, only three molecules remain—a loss of four. Thus, the ratio of the losses at the two ends is two to one—the same as the ratio of the assumed ionic velocities.

Transport Numbers.—It should be noted, however, that another cause would be competent to explain the unequal dilution of the two solutions. If either ion carried with it some of the unaltered salt or some of the solvent, concentration or dilution of the liquid would be produced where the ion was liberated. There is reason to believe that in certain cases such complex ions do exist, and interfere with the results of the differing ionic velocities. For certain concentrated solutions the transport number is found to be greater than unity; thus for a normal solution of cadmium iodide its value is 1·12. (One litre of a *normal* solution contains one gram equivalent of the dissolved substance; *see* EQUIVALENT.) This is best explained by the formation of structures represented by some such chemical formula as I (CdI_2). It is found that, in such cases as this, where it seems necessary to imagine the existence of complex ions, the transport number changes rapidly as the concentration of the original solution is changed. Thus, diminishing the concentration of the cadmium iodide solution from normal to one-twentieth normal changes the transport number from 1·12 to 0·64. Hence it is probable that in cases where the transport number keeps constant with changing concentration the hypothesis of complex ions is unnecessary, and we may suppose that the transport number is a true migration constant from which the relative velocities of the two ions may be calculated in the manner suggested by Hittorf. This conclusion is confirmed by the results of the direct visual determination of ionic velocities (*see* ELECTRICITY, CONDUCTION OF: *In Liquids*), which, in cases where the transport number remains constant, agree with the values calculated from those numbers. Many solutions in which the transport numbers vary at high concentration often become simple at greater dilution.

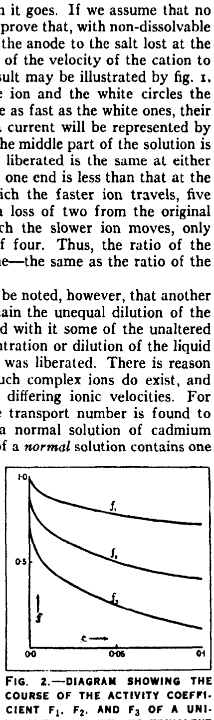

FIG. 2.—DIAGRAM SHOWING THE COURSE OF THE ACTIVITY COEFFICIENT F_1, F_2, AND F_3 OF A UNIVALENT, BIVALENT AND TRIVALENT IN PRESENCE OF A UNI-UNIVALENT SALT (AS KCL) OF THE CONCENTRATION C (IN MOLS. PER LITRE), MAKING F_1. IN 0·1 KCL ABOUT 70% F_1, IN AN ION-FREE MEDIUM, WHILE F_3 IN 0·1 KCL FALLS TO 10%

F. Kohlrausch in 1879 provided the next important step in the theory of the subject. Kohlrausch formulated a theory of electrolytic conduction based on the idea that, under the action of the electric forces, the oppositely charged ions moved in opposite directions through the liquid, carrying their charges with them. If we eliminate the polarization at the electrodes, it can be shown that an electrolyte possesses a definite electric resistance and therefore a definite conductivity. On the view of the process of conduction described above, the amount of electricity conveyed per second is measured by the product of the number of ions, (known from the concentration of the solution), the charge carried by each of them and the velocity with which on the average they move through the liquid. The concentration is known, and the conductivity can be measured experimentally; thus the average velocity with which the ions move past each other under the existent electromotive force can be estimated, and is found to be equal to the sum of their individual velocities, which can therefore be calculated. From Hittorf's transport number, in the case of simple salts in moderately dilute solution, we have the ratio between the two ionic velocities. Hence the absolute velocities of the two ions can be determined, and we can calculate the actual speed with which a certain ion moves through a given liquid under the action of a given potential gradient or electromotive force.

DISSOCIATION THEORY

The verification of Kohlrausch's theory of ionic velocity verifies also the view of electrolysis which regards the electric current as due to streams of ions moving in opposite directions through the liquid and carrying their opposite electric charges with them. There remains the question how the necessary migratory freedom of the ions is secured. As we have seen, Grotthus imagined that it was the electric forces which sheared the ions past each other and loosened the chemical bonds holding the opposite parts of each dissolved molecule together. Clausius extended to electrolysis the chemical ideas which regarded the opposite parts of the molecule as always changing partners independently of any electric force, and regarded the function of the current as merely directive. Still, the necessary freedom was supposed to be secured by interchanges of ions between molecules at the instants of molecular collision only; during the rest of the life of the ions they were regarded as linked to each other to form electrically neutral molecules.

Arrhenius.—In 1887 Svante Arrhenius put forward a new theory which supposed that the freedom of the opposite ions from each other was not a mere momentary freedom at the instants of molecular collision, but a more or less permanent freedom, the ions moving independently of each other through the liquid. The evidence which led Arrhenius to this conclusion was based on van't Hoff's work on the osmotic pressure of solutions (*see* SOLUTION). If a solution, let us say of sugar, be confined in a closed vessel through the walls of which the solvent can pass but the solution cannot, the solvent will enter till a certain equilibrium pressure is reached. This equilibrium pressure is called the *osmotic pressure* (*q.v.*) of the solution, and thermodynamic theory shows that, in an ideal case of perfect separation between solvent and solute, it should have the same value as the pressure which a number of molecules equal to the number of solute molecules in the solution would exert if they could exist as a gas in a space equal to the volume of the solution, provided that the space was large enough (*i.e.*, the solution dilute enough) for the intermolecular forces betwen the dissolved particles to be inappreciable. Van't Hoff pointed out that measurements of osmotic pressure confirmed this value in the case of dilute solutions of cane sugar.

Thermodynamic theory also indicates a connection between the osmotic pressure of a solution and the depression of its freezing point and its vapour pressure compared with those of the pure solvent. The freezing points and vapour pressures of solutions of sugar are also in conformity with the theoretical numbers. But when we pass to solutions of electrolytes we find that the observed

values of the osmotic pressures and of the allied phenomena are greater than the normal values. Arrhenius pointed out that these exceptions would be brought into line if the ions of electrolytes were imagined to be separate entities each capable of producing its own pressure effects just as would an ordinary dissolved molecule. Two relations are suggested by Arrhenius's theory. (1) In very dilute solutions of simple substances, where only one kind of dissociation is possible and the dissociation of the ions is complete, the number of pressure-producing particles necessary to produce the observed osmotic effects should be equal to the number of ions given by a molecule of the salt as shown by its electrical properties. Thus the osmotic pressure, or the depression of the freezing point of a solution of potassium chloride should, at extreme dilution, be twice the normal value, but of a solution of sulphuric acid three times that value, since the potassium salt contains two ions and the acid three. (2) As the concentration of the solutions increases, the ionization as measured electrically and the dissociation as measured osmotically might decrease more or less together.

Depression of Freezing Point.—Measurements of freezing point are at present more convenient and accurate than those of osmotic pressure, and we may test the validity of Arrhenius's relations by their means. The theoretical value for the depression of the freezing point of a dilute solution per gram-equivalent of solute per litre is 1·857° C. Completely ionized solutions of salts with two ions should give double this number or 3·714° C, while electrolytes with three ions should have a value of 5·57° C. The following results are given by H. B. Loomis for the concentration of 0·01 gram-molecule of salt to 1,000 gm. of water. The salts tabulated are those of which the equivalent conductivity reaches a limiting value indicating that complete ionization is reached as dilution is increased. With such salts alone is a valid comparison possible.

Molecular Depressions of the Freezing Point

Electrolytes with Two Ions

Potassium chloride	3·60	Nitric acid	3·73
Sodium chloride	3·67	Potassium nitrate	3·46
Potassium hydrate	3·71	Sodium nitrate	3·55
Hydrochloric acid	3·61	Ammonium nitrate	3·58

Electrolytes with Three Ions

Sulphuric acid	4·49	Calcium chloride	5·04
Sodium sulphate	5·09	Magnesium chloride	5·08

At the concentration used by Loomis the electrical conductivity was considered to indicate that the ionization is not complete, particularly in the case of the salts with divalent ions in the second list. The measurements of freezing points of solutions at the extreme dilution necessary, on the basis of the theory to secure complete ionization is a matter of great difficulty, but in researches where this difficulty has been overcome results have been obtained for solutions of sugar, where the experimental number is 1·858, and for potassium chloride, which gives a depression of 3·720. These numbers agree very closely with those indicated by theory, viz., 1·857 and 3·714, and establishes very definitely the case for complete dissociation of dilute salt solutions.

The Action of Ions.—It is necessary to point out that the dissociated ions of such a body as potassium chloride are not in the same condition as potassium and chlorine in the free state. The ions are associated with very large electric charges, and, whatever their exact relations with those charges may be, it is certain that the energy of a system in such a state must be different from its energy when unelectrified. Again, water, the best electrolytic solvent known, is also the body of the highest specific inductive capacity (dielectric constant), and this property, to whatever cause it may be due, will reduce the forces between electric charges in the neighbourhood, and may therefore enable two ions to separate. This view of the nature of electrolytic solutions at once explains many well-known phenomena. Other physical properties of these solutions, such as density, colour, optical rotatory power, etc., like the conductivities, are *additive, i.e.*, can be calculated by adding together the corresponding properties of the parts. This again suggests that these parts are independent of each other.

Electrolytes possess the power of coagulating solutions of colloids such as albumen and arsenious sulphide. The mean values of the relative coagulative powers of sulphates of mono-, di- and tri-valent metals have been shown experimentally to be approximately in the ratios 1:35:1,023. The dissociation theory refers this to the action of electric charges carried by the free ions. If a certain minimum charge must be collected in order to start coagulation, it will need the conjunction of $6n$ monovalent, or $3n$ divalent, to equal the effect of $2n$ trivalent ions. The ratios of the coagulative powers can thus be calculated to be $1:x:x^2$, and putting $x=32$ we get 1:32:1,024, a satisfactory agreement with the numbers observed.

An interesting relation appears when the electrolytic conductivity of solutions is compared with their chemical activity. The readiness and speed with which electrolytes react are in sharp contrast with the difficulty experienced in the case of non-electrolytes. Moreover, a study of the chemical relations of electrolytes indicates that it is always the electrolytic ions that are concerned in their reactions. The tests for a salt, potassium nitrate, for example, are the tests not for KNO_3, but for its ions K' and NO_3', and in cases of double decomposition it is always these ions that are exchanged for those of other substances. If an element be present in a compound otherwise than as an ion, it is not interchangeable, and cannot be recognized by the usual tests. Thus neither a chlorate, which contains the ion ClO_3', nor monochloracetic acid, shows the reactions of chlorine, though it is of course present in both substances; again, the sulphates do not answer to the usual tests which indicate the presence of sulphur as sulphide. The chemical activity of a substance is a quantity which may be measured by different methods. For some substances it has been shown to be independent of the particular reaction used. It is then possible to assign to each body a specific coefficient of affinity. Arrhenius has pointed out that the coefficient of affinity of an acid is proportional to its electrolytic ionization.

Affinities of Acids.—These have been compared in several ways. W. Ostwald (*Lehrbuch der allg. Chemie,* vol. ii., 1893) investigated the relative affinities of acids for potash, soda and ammonia, and proved them to be independent of the base used. The method employed was to measure the changes in volume caused by the action. His results are given in column I. of the following table, the affinity of hydrochloric acid being taken as one hundred. Another method is to allow an acid to act on a salt soluble only with difficulty, and to measure the quantity which goes into solution. Determinations have been made with calcium oxalate, $CaC_2O_4+H_2O$, which is easily decomposed by acids, oxalic acid and a soluble calcium salt being formed. The affinities of acids relative to that of oxalic acid are thus found, so that the acids can be compared among themselves (column II.). If an aqueous solution of methyl acetate be allowed to stand, a slow decomposition goes on. This is much quickened by the presence of a little dilute acid, though the acid itself remains unchanged. It is found that the influence of different acids on this action is proportional to their specific coefficients of affinity. The results of this method are given in column III. Finally, in column IV. the electrical conductivities of normal solutions of the acids have been tabulated. A better basis of comparison would be the ratio of the actual to the limiting conductivity, but since the conductivity of acids is chiefly due to the mobility of the hydrogen ions, its limiting value is nearly the same for all and the general result of the comparison would be unchanged.

Acid	I.	II.	III.	IV.
Hydrochloric	100	100	100	100
Nitric	102	110	92	99·6
Sulphuric	68	67	74	65·1
Formic	4·0	2·5	1·3	1·7
Acetic	1·2	1·0	0·3	0·4
Propionic	1·1	..	0·3	0·3
Monochloracetic	7·2	5·1	4·3	4·9
Dichloracetic	34	18	23·0	25·3
Trichloracetic	82	63	68·2	62·3
Malic	3·0	5·0	1·2	1·3
Tartaric	5·3	6·3	2·3	2·3
Succinic	0·1	0·2	0·5	0·6

It must be remembered that the solutions not being of quite the same strength these numbers are not strictly comparable, and that the experimental difficulties involved in the chemical measurements are considerable. Nevertheless, the remarkable general agreement of the numbers in the four columns is quite enough to show the intimate connection between chemical activity and electrical conductivity.

Ostwald's Dilution Law.—On the basis of the theory of partial dissociation of electrolytes at intermediate concentrations the ordinary laws of chemical equilibrium have been applied to the case of the dissociation of a substance into its ions. Let x be the number of molecules which dissociate per second when the number of undissociated molecules in unit volume is unity, then in a dilute solution where the molecules do not interfere with each other, xp is the number when the concentration is p. Recombination can only occur when two ions meet, and since the frequency with which this will happen is, in dilute solution, proportional to the square of the ionic concentration, we shall get for the number of molecules re-formed in one second yq^2 where q is the number of dissociated molecules in 1 cu. centimetre. When there is equilibrium, $xp = yq^2$. If μ_c be the molecular conductivity, and μ_∞ its value at infinite dilution, the fractional number of molecules dissociated will be μ_c/μ_∞, which we may write as α. The number of undissociated molecules is then $1-\alpha$, so that if V be the volume of the solution containing 1 gram-molecule of the dissolved substance, we get

$$q=\alpha/V \quad \text{and} \quad p=(1-\alpha)/V,$$

hence
$$x(1-\alpha)V = y\alpha^2/V^2,$$

and
$$\frac{\alpha^2}{V(1-\alpha)} = \frac{x}{y} = \text{constant} = K.$$

This constant K gives a numerical value for the chemical affinity, and the equation should represent the effect of dilution on the molecular conductivity of binary electrolytes.

In the case of substances like ammonia and acetic acid, where the dissociation is very small, $1-\alpha$ is nearly equal to unity, and only varies slowly with dilution. The equation then becomes $\alpha^2/V=K$, or $\alpha=\sqrt{VK}$, so that the *molecular conductivity* is proportional to the square root of the dilution V. Ostwald has confirmed the equation by observation on a large number of weak acids (*Zeits. physikal. Chemie*, 1888, 1889). Thus in the case of cyanacetic acid, while the volume V was changed in stages by doubling from 16 to 1,024 litres, the values of $K\times 10^5$ were 376, 373, 374, 361, 362, 361, 368. The mean values of $K\times 10^5$ for other common acids were: formic, 2·14; acetic, 1·80; monochloracetic, 155; dichloracetic, 5,100; trichloracetic, 121,000; propionic, 1·34. From these numbers we can by help of the equation calculate the conductivity of the acids for any dilution. The value of K, however, does not keep constant so satisfactorily in the case of highly dissociated substances. The anomalies in the dilution law when applied to strong electrolytes, have now been elucidated by means of the theory of complete dissociation.

Degree of Dissociation.—According to the law put forward by Kohlrausch of the independent migration of ions, it follows that the equivalent conductivity of an electrolyte is given by the expression:

$$\Lambda_0=(u+v)F,$$

where Λ_0 is the equivalent conductivity at the limiting dilution when the electrolyte is completely dissociated, u and v are the velocities of anion and cation respectively in cm. per sec. for a potential gradient of 1 volt per cm. and F is the faraday or number of units of current associated with 1 gm. equivalent of matter. In accordance with the theory of partial dissociation for a degree of dissociation α, the quantity of electricity transported by the ions will be given by $\Lambda_c=(u+v)\alpha F$, where Λ_c is the equivalent conductivity for the concentration c. This law has been found to be closely followed in that the conductivity of any given ion is independent of the nature of an ion of opposite polarity with which it is associated. On dividing this equation by the preceding one, we obtain

$$\alpha=\Lambda_c/\Lambda_0,$$

or the degree of dissociation is expressed in terms of the *equivalent conductivity ratio*. In this derivation, however, it is assumed that the velocities of the ions are independent of the concentration.

The *viscosity* of the electrolyte may, however, change with the concentration and accordingly the velocities will require the foregoing expression to be modified to

$$\alpha=\Lambda_c/\Lambda_0, \quad \eta_c/\eta_0,$$

where η_c and η_0 represent the viscosity of the solution and the solvent respectively. To correct for the effect of varying viscosity Washburn (*J. Amer. Chem. Soc.*, 1911) suggests for calculating ionization the equation

$$\Lambda/\Lambda_0\,(\eta/\eta_0)^m,$$

and shows that the value of m never differs from unity by more than 0·2. The calculation of ionization from the equivalent conductivity ratio or the equivalent conductivity-viscosity ratio may be affected by the influence on mobility exerted by the electric charge on the ions as is discussed below, or by changes in the chemical composition of the ions. A decrease in the hydration of the ions takes place in many cases at high concentration and this will presumably cause an increase of the mobility.

Hydrolysis.—A further important chemical change is hydrolysis, which takes place especially with salts of weak acids or bases. The following table shows the percentage hydrolysis (100 h) calculated by the approximate mass-action equation,

$$\frac{h^2}{1-h} = \frac{K_w}{c\,K_{A \text{ or } B}}$$

where K_w, K_A and K_B are the ionization (or dissociation) constants of water, acid and base respectively. The value of K_w is taken as 10^{-14}.

K_A or K_B	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}
0·1 N . . .	0·0032	0·0100	0·0316	0·100	0·316
0·01 N . . .	0·0100	0·0316	0·100	0·316	0·995
0·001 N . . .	0·0316	0·100	0·316	0·995	3·11
0·0001 N . . .	0·100	0·316	0·995	3·11	9·51

Another uncertainty of a different nature involved in the calculation of variation from the equivalent conductivity ratio arises from the fact that the maximum value of Λ is not fully attained even at the smallest concentrations at which accurate measurements have so far been made and that therefore, Λ_0 must be obtained by extrapolation from the Λ values at higher concentrations. In this derivation it is necessary to assume that the fractional relation between equivalent conductivity and concentration, which is found empirically to hold at higher concentrations, continues to hold down to zero concentration.

Change of Equivalent Conductivity.—To express the change of equivalent conductivity with concentration use has generally been made of the function $c(\Lambda_0-\Lambda)=K(c\Lambda)^n$ which corresponds to the ionization relation $(c\alpha)^n/c(1-\alpha)=K$. It is found, however, that the values of n for the concentration intervals 0·1–20 and 10–200 milli-equivalents per litre as a rule differ considerably, showing that the function $(c\Lambda)^n=Kc(\Lambda_0-\Lambda)$, or its equivalent $(c\alpha)^n=Kc(1-\alpha)$ with a single value of the exponent, does not express the change of equivalent conductivity satisfactorily through the range of concentration from 0·0001 to 0·2 normal. At lower concentrations, however, the values of n become nearly identical and equal to about 1·5 for both mono- and divalent salts. A relation found by Kohlrausch to apply closely for many univalent salts between the concentrations 0·001 and 0·1N is of the form $\Lambda=B-KC^{\frac{1}{2}}$. It is found that by correcting for viscosity the term Λ_n/η_0 is closely proportional to the concentration for uni-univalent salts between the concentrations of 1 and 200 millinormal but that considerable deviations occur with uni-bivalent salts.

THEORY OF COMPLETE DISSOCIATION

The classical theory of Arrhenius may be summarized as

having correlated the experiments of Kohlrausch and van't Hoff, postulated a very considerable degree of dissociation in aqueous solutions of salts at ordinary concentrations, and provided a method of calculating the degree of dissociation. The theory accounted for and correlated three common properties of acids, bases and salts, namely, (1) the practically instantaneous exchange of radicals, as compared to the slow reactions of organic chemistry, (2) the increase in equivalent conductivity with dilution to a finite limit set by the mobilities of the ions, (3) van't Hoff's observation that the osmotic properties of this class of substances always exceeded that predicted by his gas law equation $\pi = cRT$, which he had demonstrated was valid for non-electrolytes in dilute solution.

The net results of recent research have shown that the behaviour of the typical strong electrolytes in solvents of high dielectric constant is best explained by the assumption of a complete, or at least practically complete, ionization, while the ionization theory retains its original form in all essential details when applied to weak electrolytes (*cf.* J. N. Brönsted and V. K. La Mer, *J. Amer. Chem. Soc.*, 1924; V. K. La Mer, *Trans. Amer. Electrochem. Soc.*, 1927). In the Arrhenius theory, the degree of dissociation α is, as shown above, calculated from either the conductivity ratio μ_c / μ_0 or Λ_c / Λ_0, where Λ_c is the equivalent conductivity at the concentration c, or from van't Hoff's factor i in the osmotic equation for electrolytes

$$\pi = ic\,RT \tag{1}$$

for according to Arrhenius i is to be interpreted as the quotient of the number of particles present divided by the number which would be present if no dissociation had occurred. If each individual particle behaved independently of its neighbours, *i.e.*, obeyed the gas laws as given by van't Hoff's law then Arrhenius's interpretation of the meaning of i would be valid. However, as is discussed later, the electric charges upon the ions set up electrostatic fields, which do not allow the ions to behave independently as demanded by the gas laws. The effects of these interionic attractions were neglected in the development of the classical theory, whereas, according to the modern point of view, the anomaly of strong electrolytes is to be attributed entirely to their operation. If Arrhenius's assumption in regard to the interpretation of i were correct we should obtain for a salt dissociating into ν ions that

$$\alpha = \frac{i-1}{\nu-1} \tag{2}$$

and from Ostwald's dilution law, as shown previously, we should find that

$$K = \frac{\alpha^2 c}{1-\alpha} = c\,\frac{\left(\dfrac{\Lambda_c}{\Lambda_0}\right)^2}{1-\left(\dfrac{\Lambda_c}{\Lambda_0}\right)} \tag{3}$$

In the following tables the first summarizes the results from conductivity measurements upon the typical weak electrolyte acetic acid.

Values of K for acetic acid in water at 25° C

V is the volume containing 1 mol. Data by Kendall

Since an approximately constant value of K is obtained for solutions up to 0·1M, the applicability of the Arrhenius theory must be regarded as established for this class of electrolyte to the concentration indicated. On the other hand the second table shows that large deviations occur in the value of K for the typical strong electrolytes potassium chloride and hydrogen chloride, and the Ostwald dilution law breaks down completely for other strong electrolytes. For instance in the case of high valence salts, like $K_4F_e(CN)_6$ and $La_2(SO_4)_3$, K varies about one-million-fold for the same range of concentration.

Explanations of Deviations from Ostwald's Law.—Attempts were for many years made to reconcile these deviations by assuming changing viscosity of the solution, solvation of ions, and compound formation between solvent and solute. The difficulty has, however, only been overcome by adopting a separate theoretical treatment for strong and weak electrolytes. One reason for the reluctance in abandoning the classical view of a considerable, yet substantially incomplete, dissociation of strong electrolytes was that, the values of α calculated from the conductivity ratio and those calculated from the freezing point measurements using equation (2) usually agreed very closely. However, more accurate data recently obtained, particularly with the higher valence types of salts, has shown that the agreement is in general not good. The best experimental data indicate that for 0·1N HCl

$$\frac{\Lambda_c}{\Lambda_0} = 0{\cdot}9207, \qquad \frac{i-1}{\nu-1} = 0{\cdot}917 \text{ (from freezing point)}$$

while the electromotive force measurements upon $H_2-HCl-AgCl$ cells would indicate a value of 0·804. G. N. Lewis has shown that very close agreement is obtained between data from freezing point determinations when treated by strict thermodynamic methods, and e.m.f. data but not with that derived from the conductivity ratio.

The main theories which have adopted the assumption first put forward by Sutherland (*Phil. Mag.*, 1902, 1906) that complete dissociation occurs with strong electrolytes are those of Bjerrum, Milner, Ghosh and Debye and Huckel. Bjerrum was led to this point of view from the observation that the optical properties of solutions of the complex chromium salts are practically independent of the concentration. Milner (*Phil. Mag.*, 1912, *Trans. Faraday Soc.*, 1919) first put forward the theory that the fall in conductivity with increasing concentration is due to a decrease in the mobility of the ions through the influence of inter-ionic forces which cause an increase in the occurrence of the association of the ions. The term *virial* is used to denote the electrostatic forces of an ion multiplied by the distance over which it acts. Values for the molecular lowering of the freezing point are accounted for quantitatively by the theory but no expression has been derived by it to enable the evaluation of conductivity as a function of concentration.

In a theory of Ghosh (*Trans. Chem. Soc.*, 1918), a new departure is made in the representation of the properties of electrolytes. Complete ionization of electrolytes is assumed, and from a consideration of the electrostatic energy of an ionized electrolyte, simple equations are derived to express electrolytic conductivity in aqueous and non-aqueous solutions. On the basis of this hypothesis, the following expressions are derived to express the relation between conductivity and the physical properties of the solution: For binary electrolytes:

$$\frac{Ne^2\sqrt[3]{2N}}{D\sqrt[3]{V}} = 2RT\log_e\frac{\mu_0}{\mu_c}$$

and for ternary electrolytes:

$$\frac{3Ne^2\, 2\sqrt[3]{2N}}{D\sqrt{3}\sqrt[3]{V}} = 3RT\log_e\frac{\mu_0}{\mu_c}$$

where N is Avagadro's number ($6{\cdot}16\times 10^{23}$), e the charge on a univalent ion ($4{\cdot}7\times 10^{-10}$ e.s.u.), D the dielectric constant of the solvent and V its molecular dilution, R the gas constant $= 8{\cdot}315\times 10^{-7}$ in c.g.s. units. These expressions have been found applicable to a large number of aqueous and non-aqueous solutions.

Further considerations that support the theory of complete dissociation are such general observations as the fact that aqueous solutions of the halogen acids exhibit no appreciable vapour pressure of the hydrogen halide below a concentration of 3M., and experiments which have shown that the salt $AgClO_4$ is completely extracted by water from benzene in which it is quite soluble. The studies of the Braggs (W. H. Bragg and W. L. Bragg, *X-ray and Crystal Structure,* 1924) and others on the structure of crystals by means of X-rays furnishes more conclusive evidence for the new point of view. They find that no molecules of NaCl are present in the solid salt; instead the crystal structure consists of sodium and chlorine ions arranged in a cubic lattice, such as that each sodium ion is surrounded at equal distances by six chlorine ions and similarly each chlorine ion by six sodium ions. That the forces holding a crystal of salt together are due to the electrostatic forces between the charged ions has since been established by the calculations of Born, Debye and Scherrer, Fajans, Madelung, and others upon the magnitude of the so-called space lattice energy.

The Activity Coefficient.—(*Cf.* A. A. Noyes and D. A. MacInnes, *J. Amer. Chem. Soc.,* 1920.) The term activity is defined by G. N. Lewis as the quantity which, when substituted for the concentration of the substance in mass-action expressions, will express its effect in determining the equilibrium. Thus the activity of the substance is its effective concentration from this mass action viewpoint and determines the equilibrium of all chemical reactions between salts, acids and bases, and also the magnitude of many physical properties thermodynamically related to the activities. The relative activities of a substance in solution at different concentrations may be determined from its vapour pressure where this is appreciable. A method of more general applicability which has also a thermodynamical basis, is by e.m.f. measurements which are determined by the expression

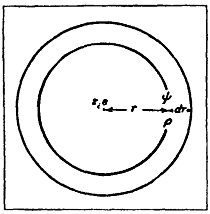

FIG. 3.—DIAGRAM ILLUSTRATING THE DENSITY OF ELECTRIC CHARGE, ρ PRODUCED BY AN ION OF VALENCY z_i AND CHARGE z_ie AT DISTANCE r

$$-\Delta F = RT\log\frac{\xi_1^+\xi_1^-}{\xi_2^+\xi_2^-}$$

where ΔF is the change of e.m.f. with a change of concentration and ξ_1^+, ξ_1^-, ξ_2^+, ξ_2^-, the activities of the ions at the two concentrations. The activity ξ can be replaced by the product cf, in which the quantity f, called the ***activity coefficient,*** is the factor by which the total concentration c, of the substance must be multiplied to give the activity of the ion, or $f=\xi/c$.

With dilute solutions of electrolytes, the value of f (solute) may be regarded on the basis of the Arrhenius theory as the thermodynamic or true degree of dissociation. Measurements of activity coefficients made with sodium, potassium and hydrogen chlorides show that the activity coefficient decreases with increasing concentration much more rapidly than does the equivalent conductivity—viscosity ratio (*i.e.,* the ratio Λ_c/Λ_0 multiplied by the ratio η_c/η_0 of the viscosity of the solution to that of water). With all substances except potassium chloride the activity coefficient, unlike the equivalent conductivity-viscosity ratio, passes through a pronounced minimum in the neighbourhood of 0·5 molal (gram-molecules per litre), afterwards increasing rapidly at the higher concentrations and in some cases exceeding the value of unity. Potassium chloride has a minimum activity coefficient in the neighbourhood of 2N. The activity coefficient, even at moderate concentrations, varies considerably with the nature of the substance; thus its value at 0·5M is 65% for potassium chloride, 73% for lithium chloride and 77% for hydrogen chloride and for potassium hydroxide.

The activity of a component in a solution can be defined most simply by the relation

$$\bar{F} = RT\ ln\ \xi + \bar{F}^0, \tag{4}$$

where ξ is the activity and $\bar{F}$ is the partial molal free energy or Gibbs chemical potential. The activity is consequently a thermodynamic quantity having the dimensions of a concentration, and is determined by the work which is necessary to transport reversibly a gram mol. of the component at constant temperature from some standard reference state, whose partial molal free energy is represented by $\bar{F}^0$, to the given state under consideration.

Since van't Hoff demonstrated that the behaviour of any solute, regardless of its specific characteristics, continuously approaches and finally obeys the gas laws when its concentration in a given solvent approaches a zero value, the most convenient reference state for solutes is one for which the activity of the solute becomes equal to the concentration at infinite dilution. In the case of strong electrolytes where independent means of determining the true concentration of the undissociated molecule are lacking, the standard state of the undissociated molecule is chosen such that the dissociation constant K becomes unity.

Fig. 2 summarizes the general results of the course of the activity coefficient with concentration f_1, f_2, and f_3 refer to the activity coefficient of a univalent, bivalent and trivalent ion or, what amounts to the same thing, the mean (geometric) activity coefficient of the ion comprising a uni-univalent, bi-bivalent or a tri-trivalent salt. A *uni-univalent salt* is one in which both ions are univalent, *e.g.,* sodium chloride. In this figure the salt or ion is present in very small amount in a solution of a uni-univalent salt of concentration c expressed in gram mols. per litre. When a univalent ion is dissolved in 0·1M KCl its activity coefficient is about 70% of its value in an ion-free-medium, while in the case of a trivalent ion the activity coefficient falls to 0·10 at $c=0{\cdot}1$M. This means that the solubility of a tri-trivalent salt is ten times as great in 0·1N KCl as in pure water. We also find as the concentration decreases that the limiting tangent for f assumes an infinite value, just as it did for the osmotic coefficient discussed previously. Obviously, the same objections to the classical theory hold for the activity coefficient of an ion (or salt) as for the osmotic coefficient, since the classical theory demands a finite limiting slope.

Ionic Strength.—When the salt acting as the solvent is of a valency type higher than the uni-univalent or when it is composed of a mixture of salts of different valence types the problem becomes more complex. From a study of the data available in 1921 Lewis and Randall, however, were able to formulate a remarkably simple law which holds in the majority of cases studied thus far; namely that in dilute solutions the activity coefficient of a given strong electrolyte is the same in all solutions of the same ionic strength. The ionic strength μ is defined as one-half the sum of the stoichiometric molar concentration of each ion multiplied by the square of its valency or charge. Thus:

$$\mu = \tfrac{1}{2}(m_1z_1^2 + m_2z_2^2 + m_3z_3^2 + \cdots) = \tfrac{1}{2}\Sigma_1^i m_iz_i^2, \tag{5}$$

where z is the valency and m the molar concentration. That is to say, if $MgCl_2$ were employed as the solvent salt in fig. 2 instead of NaCl we should use the ionic strength of the solution instead of the molar concentration, which in this particular case multiplies the concentration scale by the factor 3. If a (2–2) or (3–1) solvent salt had been used the corresponding factors would be 4 or 6 respectively. If the concentration of the ions or the salt whose activity coefficient is measured is present in appreciable amounts, it must be included in the summation in

addition to the solvent salts to determine the ionic strength. The generalization that the activity coefficient of an ion is determined in dilute solution solely by its valency and the numbers and valencies of all the surrounding ions, and not by specific individual properties as is the case in weak electrolytes, constitutes the strongest evidence for the theory that in strong electrolytes the anomalies are due to electrical effects and not to incomplete dissociation.

Interionic Attraction.—In the theory of Debye and Hückel the properties of electrolytes are elucidated by a consideration of the interionic attraction principle of ionized solutes (Debye, *Phys. Zeit.*, 1924; La Mer *loc. cit.;* A. A. Noyes, *J. Amer. Chem. Soc.*, 1924). The main idea underlying the calculations is that, owing to electrical attractions, an ion of a given sign will on the average be surrounded by more ions of unlike sign than by ions of like sign. The extent of the deviation of the gas laws in terms of the activity coefficient of the ions, or the osmotic deviation of the solvent, is calculated from the following standpoint. When a solution is diluted to a very large volume the ions become separated to such an extent that their mutual electrostatic attractions are no longer of significance, and a uniform random distribution thus prevails, or in other words the gas laws are valid. A determination is then made of the excess electrical work which is involved in this isothermal dilution, due to the rearrangement of the relative position of the ions.

A derivation is made of the energy effect due to electrical forces between the ions by means of two general principles. One, the so-called Boltzmann's principle, is borrowed from the kinetic theory, and the other, known as Poisson's equation, is derived from the laws of electrostatics and involves Coulomb's law. The following considerations will become clearer by reference to fig. 3. In this figure the dot at the centre represents an ion of valency $+z_i$ and charge $+z_ie$, and this produces in a shell of volume dv situated between the distances r and $r+dr$, a potential ψ and a density of electric charge ρ.

The *Boltzmann principle* may be stated as follows: When a large number of molecules possessing an average kinetic energy $\frac{3}{2}kT$ are distributed throughout a region in which there prevail at different points different fields of force (and therefore, different electric potentials) whereby any kind of molecule A in any given volume-element dv acquires a potential energy E, the number of such molecules will equal the number n_A per unit volume in a place where this energy is zero, multiplied by the factor $\epsilon^{-E/kT}$ and by the volume dv.

The following expression for a uni-univalent electrolyte is obtained for the density of free electricity ρ in a unit of volume (1 cu.cm.) of solution;

$$\rho = ne(\epsilon^{-e\psi/kT} - \epsilon^{+e\psi/kT}) = -2ne\left(\frac{e\psi}{kT}\right) \tag{6}$$

where n is the total number of ions present. The electrical potential ψ and the density of electricity ρ are connected by the *Poisson equation* of electrostatics; viz.:

$$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d\psi}{dr}\right) = \frac{d^2\psi}{dr^2} + 2\frac{d\psi}{rdr} = -\frac{4\pi\rho}{D}, \tag{7}$$

where r is the distance, and D the dielectric constant. This differential equation shows how the potential gradient, or field strength, $d\psi/dr$ varies with the electric density ρ and the distance r. From this equation Debye and Hückel derive the expression:

$$\rho = -\frac{e\psi}{kT}\Sigma nz_i^2 \tag{8}$$

Substituting this value of ρ in equation (7) and writing a single constant χ^2 in place of the resulting coefficient of ψ we have

$$\chi^2 = \frac{4\pi e^2}{DkT}\Sigma n_i z_i^2. \tag{9}$$

By integration, the following expression is derived for the total potential

$$\psi = \frac{e}{Da_i} - \frac{e\chi}{D}\cdot\frac{1}{1+\chi a} \tag{10}$$

where a_i is the average apparent diameter, or closest distance of approach of the ions. The first member in (10) represents the potential of an ion in an ion-free medium of dielectric constant D, where it is not influenced by surrounding ions, the second number consequently represents the potential ψ_i at the surface of the ion, due to the presence of the surrounding atmosphere of ions. When the concentration is small, χ is small and equation (10) reduces to

$$\psi_i = -\frac{e}{D}\chi. \tag{11}$$

In the general case the potential at the surface of an ion due to the ionic atmosphere is given by

$$\psi_i = \frac{z_ie\chi}{D}\cdot\frac{1}{1+\chi a_i} \tag{12}$$

which at low concentrations reduces to

$$\psi_i = \frac{-z_ie\chi}{D}. \tag{13}$$

From equation (9) it is seen that $1/\chi$ has the dimensions of distance, and by its use Debye and Hückel avoid the introduction of an average distance between ions based upon the cube root of the concentration. They show further that the use of such an average distance is incorrect, since the ions are not restricted to oscillating above fixed points as in a crystal, but are free to move about. $1/\chi$ which corresponds to the thickness of the Helmholtz double layer is therefore called a *characteristic or probability distance*, and is more exactly defined as the distance at which the potential difference has fallen to $1/\epsilon$ of its value due to the distribution of the surrounding ions. For aqueous solutions (9) yields for a uni-univalent salt

$$\chi = 0{\cdot}327\times10^{-8}\sqrt{m}\ \text{cm.}^{-1}, \tag{14}$$

where m is the molar concentration and may be replaced by the ionic strength μ. In general

$$\chi = 0{\cdot}327\times10^{-8}\sqrt{\mu}\ \text{cm.}^{-1} \tag{15}$$

$1/\chi$ is about ten times the diameter of an ion at $0{\cdot}01\mu$ but of the same order of magnitude as an ion for a $1{\cdot}0\mu$ solution.

Having determined ψ_i the potential at the surface of an ion due to the ionic atmosphere, Debye (*Physik Z.*, 1924), shows that the electrical work of dilution is equal to the work required to build up at a finite concentration the Boltzmann distribution, by charging the ions isothermally and reversibly from zero potential to ψ_i. The electrical free energy of dilution F_e then becomes

$$F_e = \sum_{i=1}^{s}\tfrac{1}{2}\cdot n_iez_i\psi_i = -\frac{kT\chi^3}{12\pi} \tag{16}$$

where $\sum_{i=1}^{s}$ represents the summation of the different types of ions present of. the number per cu. cm., $n_1 \cdots n_i \cdots n_s$. By adding the quantity F_e to the classical expression for the free energy of an ideal solution we obtain the free energy F of an ionic solution.

The activity of a component in a solution can be defined most simply by the relation of G. N. Lewis

$$\overline{F} = RT\ ln\ \xi + \overline{F}_0,$$

where ξ is the activity, $\overline{F}$ is the partial molal free energy, or Gibbs chemical potential, and $\overline{F}_0$ is the partial molal free energy of some standard reference state, such as that of a high degree of dilution when the gas laws are obeyed. The activity coefficient f_i for an ion of the i^{th} sort may be defined by the relation

$$\overline{F}_e = \frac{\delta F_e}{\delta n_i} = kT\ ln\ f_i$$

where $\overline{F}_e$ is the partial molal electrical free energy of that ion. From the above and equation (16) we have

$$-ln\ f_i = \frac{z_ie^2}{2DkT}\chi. \tag{17}$$

When the concentration is expressed as the ionic strength (*cf.* equation 5) in mol. per litre, and χ is replaced by equation (14) the following simple limiting expression is obtained for the activity coefficient of an ion in aqueous solution at 25° C;

$$-\log_{10} f_i = \frac{3\alpha}{2\cdot 3} z_i^2 \sqrt{\mu}, \tag{18}$$

which is valid for high dilutions where the individual properties, such as ionic size, may be neglected,

$$\alpha = N^2 e^3 \sqrt{2\pi}/(10 R D_0 T)^{3/2}, \tag{18a}$$

N being the Avagadro number and R the gas constant per gram. mol. For the usual case of a salt composed of two kinds of ions of valencies z_1 and z_2 respectively the equations of Debye and Hückel yield finally

$$-\log_{10} f_{(ion)} = \frac{3}{2\cdot 3}\alpha z_i^2 \sqrt{\mu} = 0{\cdot}5 z_i^2 \sqrt{\mu} \text{ in aqueous solution} \tag{19}$$

$$-\log_{10} f_{(salt)} = \frac{3}{2\cdot 3}\alpha(-z_1 z_2)\sqrt{\mu} = 0{\cdot}5 z_1 z_2 \sqrt{\mu} \text{ in aqueous solution.} \tag{20}$$

In place of the activity coefficient, use is frequently made of the *osmotic coefficient* which may be derived from the relation $\phi = i/\nu$, where i is defined in equation (1) and ν is the number of ions into which the salt dissociates. The osmotic coefficient is thus the factor necessary to convert the ideal (van't Hoff) osmotic pressure $\bar{\pi}$ to the observed value π, or, in terms of freezing-point measurements, it is the ratio of the observed molal lowering to the theoretical value for the molal lowering.

Thus: $$\pi = \phi\bar{\pi} = \phi cRT$$

or $$\frac{\bar{\pi} - \pi}{\bar{\pi}} = 1 - \phi = \text{osmotic deviation.}$$

From the square root dependence of $ln\, f$ upon the concentration the following relation obtains

$$-ln\, f = 3(1-\phi)$$

Accordingly from (14)

$$1 - \phi = \alpha(-z_1 z_2)\sqrt{\mu} = 0{\cdot}38(-z_1 z_2)\sqrt{\mu} \text{ in aqueous solution} \tag{21}$$

The above deductions have so far related only to ideal salt solutions in which the dimensions of the ions are negligible in comparison with the characteristic distance $1/\chi$. When the concentration becomes of the order of $0{\cdot}01\mu$ or greater it is no longer permissible to neglect the factor $1/(1+\chi a_i)$ in the expression (12) for the potential. In the evaluation of the activity coefficient the factor involving a retains the same form, and instead of (20) we have

$$-\log_{10} f = 0{\cdot}5(-z_1 z_2)\sqrt{\mu}\,\frac{1}{1+0{\cdot}327 a\sqrt{\mu}}. \tag{22}$$

As an expression valid for more concentrated solutions, a is an average value for all the individual a_i values expressed in A.U. (10^{-8} cm.) units and may be considered as the distance of closest approach of two ions. A consideration of these equations shows that if we plot either $-\log_{10} f$ or $1-\phi$ against the square root of the concentration, the data should fall upon a straight line the slope of which is determined solely by the valencies, the dielectric constant of the solution and the absolute temperature.

The simplest and most useful method of testing the relation expressed in equation (14) in very dilute solutions consists in determinations of the solubility of very sparingly soluble salts in solutions of other salts of varying concentration. It follows from thermodynamical principles that the activity of a solute in a saturated solution must always equal the activity of the solid solute. If in a saturated solution the ions of the saturating salt have the mobilities m_1 and m_2, the numbers per molecule of the ions n_1 and n_2 and the corresponding activity coefficients f_1 and f_2, then the equation $m_1^{n_1} m_2^{n_2} f_1^{n_1} f_2^{n_2}$ = constant holds thermodynamically at constant temperature. If various foreign substances (either electrolytes or non-electrolytes) are added to a solution in equilibrium with a solid phase, the stoichiometric solubility (s) changes but the activity of the dissolved particles saturating the solution remains the same, *i.e.*,

$$f_0 s_0 = fs$$

where f_0 is the activity coefficient and s_0 the solubility in what is otherwise pure water, while f and s refer to these values in a solvent prepared by adding foreign substances to the solution. In the ideal region and for no ion in common, the relation becomes

$$ln\, s/s_0 = ln\, f_0 - ln\, f = \alpha z_1 z_2(\sqrt{\mu} - \sqrt{\mu_0}) \tag{23}$$

where μ and μ_0 are the ionic strengths in the two media. The limiting laws have been tested at high dilutions by Brönsted and La Mer by determining the increase in solubility of certain difficultly soluble colbaltammine salts ($s_0 = 0{\cdot}00054$ to $0{\cdot}00005$M) on the addition of small amounts ($0{\cdot}0005$ to $0{\cdot}01$M) of foreign salts which do not interact chemically with the saturating salt. Fig. 4 where $-\log_{10} f$ is plotted against $\sqrt{\mu}$ summarises the results for very high dilutions.

These data verify the theory in the following respects: (1) The value of α as calculated by the theory is correct within the limits of error for which D is known for pure water since the slope of line (1) equals 0·50. (2). The valence factor $z_1 z_2$ (z_i^2 for a single ion) is correct, since the slopes of the lines are in the corresponding ratios 1:2:3:9. (3) The principle of ionic strength is valid for the simpler types considered, since the values of f when compared for different solvent salts at the same ionic strength agree among themselves for a saturating salt of a given valence type. The theory as developed above deals only with the so-called ideal salt solutions, where the properties of the solution depend simply upon the numbers and valencies of the ions. With rising concentration the activity coefficient depends to an increasing degree upon the chemical character of the ions in solution and particularly on the influence of ionic size. For these solutions the expression given in equation (22) is applicable. Further confirmation of the validity of the Debye theory is obtained from the concordance in the values of a, the mean effective diameter of the ions, as determined from freezing point and from solubility measurements.

The simple form of the Debye theory has been extended by Hückel to more concentrated solutions by introducing the assumption that the dielectric constant is a linear function of the concentration of ions. The following equation is derived:

$$-\log_{10} f = \frac{(-z_1 z_2)\alpha\sqrt{\mu}}{1+0{\cdot}327 a\sqrt{\mu}} + B2c,$$

where B is a function depending on the dielectric constant and c is the concentration in molecules per litre. This expression differs from equation (22) by the added term $B2c$. This equation has been found to give a good representation of the data for a number of solutions.

Ion Association.—Bjerrum has developed a hypothesis according to which a state of association is to be regarded as existing between two ions when their distance of separation is less than a certain critical minimum. The law of mass action is considered applicable to the association equilibrium. A consideration which arises from this hypothesis is whether this view of ion-association merely states the classical view of incomplete dissociation in its converse form. However although an associated ion pair may be regarded as physically identical with an undissociated molecule of salt, a distinction between the two views is to be made from the standpoint of the molecular forces involved. The forces which produce ion-association obey Coulomb's law and vary as the inverse square of the distance, whereas the forces involved in a true dissociation equilibrium must vary according to a much higher inverse power of the distance. A discrete energy difference must exist between undissociated molecules and their ions, while the difference in energies between associated and free ions will vary continuously, depending on the distance of separation.

It seems logical to assume that even with a completely ionized salt such as potassium chloride, occasionally a K′, and Cl′ ion may collide under such favourable circumstances that a rearrangement in electron orbits occurs, whereby a true undissociated molecule

possessing a pair of shared electrons is formed. The reciprocal of the dissociation constant of the mass action function is a measure of the number of such molecules. With hydrogen and acetate ions it is very frequent, since $K = 1{\cdot}8 \times 10^{-5}$. With the strong electrolytes the probability would be vanishingly small and in an ideal strong electrolyte zero. It has been computed by different methods that the true dissociation constant of HCl in water is of the order of 10^6 to 10^7. This means that the probability of the existence of an undissociated molecule of HCl is only about one in a million when the total concentration is one molar. Knight and Hinshelwood (*J. Chem. Soc.*, 1927) from the distribution of HCl between benzene and water find that the transition to the non-polar form occurs at about 13 molar in water. In the case of most salts the probability that its ions will share an electron pair is without doubt much less, so small in fact, that it is a question of no immediate practical importance whether we consider potassium chloride to be completely ionized or whether we say it is only practically completely ionized.

MODERN THEORY OF POLARITY

Until recently the source of the opposite electric charges on the ions of dissociated compounds remained obscure, but their origin has now been satisfactorily explained from a consideration of the physical theories which have been developed to account for the structure of the atom. According to present theories which have been developed by J. J. Thomson (*Phil. Mag.* 1914), Kossel (*Ann. Physik,* 1916), G. N. Lewis (*J. Amer. Chem. Soc.*, 1916), and I. Langmuir (*Ibid.*, 1920), the atom consists of a nucleus which remains unaltered in all ordinary chemical changes, and possesses an excess of positive charges corresponding in number to the ordinal number of the group in the periodic table to which the element belongs (*see* PERIODIC LAW). The nucleus is surrounded by negative charges or electrons which, on the Lewis-Langmuir theory are maintained in definite positions through the equilibrium between the opposing influences of the electro-static attraction of the central charge and the mutual repulsion of the ions (*see* VALENCY). A further factor which operates in this equilibrium is a force of repulsion which appears between nucleus and ion at very short intervals of separation. The number of electrons in

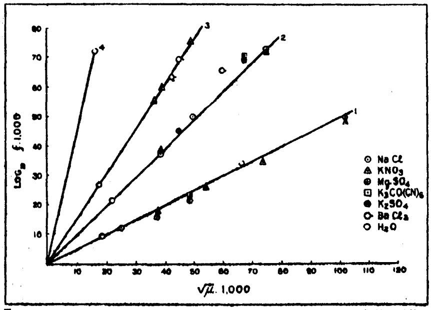

FIG. 4.—GRAPHS SHOWING THE RELATION BETWEEN SOLUBILITY AND IONIC STRENGTH OF SLIGHTLY SOLUBLE COBALTAMINE SALTS OF DIFFERENT VALENCE TYPES IN THE PRESENCE OF SECOND SALTS OF VARYING VALENCIES; NO. 1.—$Z_1=1$; $Z_2=1$: NO. 2.—$Z_1=1$: $Z_2=2$: NO. 3.—$Z_1=1$; $Z_2=3$: NO. 4.—$Z_1=3$; $Z_2=3$

the outer layers are, in the neutral atom, equal in number to the excess of positive charge of the nucleus, but the number of electrons in the shell may vary during chemical change between 0 and 8. A group of eight electrons forms a complete shell and, according to the number of these shells, gives one of the inert elements, helium, neon, argon, krypton or xenon. All atoms tend to attain the electron configuration of the inert gases, because these configurations are the most stable; therefore all atoms attempt, either to give up all the valence electrons (electro-positive valence) so that each arrives at the electron number of the proceeding inert gas, or to take on so many electrons that the outer electron group will be brought up to the number of electrons of the next higher inert gas. Chemical attraction between two atoms may accordingly arise from one or two mechanisms. (1) The tendency of one atom to complete its shell of electrons at the expense of a second atom, thus leaving one atom with an excess of positive charges and the second with an excess of negative charges. The electrostatic attraction thus produced maintains the combination. The number of electrons which may be detached or acquired by this process is a measure of the valency of the element. This type of union occurs in such a compound as hydrogen chloride, the hydrogen having released its single electron to supplement the seven electrons around the chlorine and complete its octet. On account of the unsymmetrical nature of the hydrogen atom the electron is readily lost, leaving the residue a positively charged hydrogen ion. (2) The atoms may orientate themselves in such a manner that from one to four electrons of each atom may be shared or held in common in the structure of both atoms. In this way the shells of electrons are completed to form stable groups without disturbing the electrical neutrality of the system.

In the first type of combination the valence electron is almost completely removed from the one atom and enters the assemblage of the other. Such compounds, which are said to be ***hetero-polar or polar***, and decompose with relative ease into ions, are held together mainly by Coulombian electrostatic forces. In the second type, sometimes known as covalency, the valence electrons describe such orbits in the compound that they belong equally to both atoms; since these atoms have the same electric charge, such compounds are called *homopolar or non-polar.* They show no tendency to dissociate into ions. A large portion of the chemical compounds can be classified in these two limiting groups without much difficulty. Rigorously homo-polar compounds exist only in the union between the two atoms of the same species such as in H_2, O_2 N_2. As soon as different kinds of atoms combine, some dissymmetry in the division of the electric charges can always be observed by such means as the existence of an infra-red spectrum. The difference between the above two types can thus only be regarded as one of degree and not of kind.

According to a representation of Lewis and Randall (*J. Amer. Chem. Soc.*, 1921), if we have a uni-univalent electrolyte whose cation is M and whose anion is X, the molecule may be represented by the formula $M{:}\ddot{\underset{..}{X}}{:}$, where the pairs of dots represent the valence electrons, or the electrons of the outer shells. The pair lying between the atomic nuclei M and X constitutes the chemical bond. In the weak electrolytes, like acetic acid or mercuric chloride, this approximates to the typical bond of organic chemistry, but as we pass to stronger electrolytes the nucleus of the cation draws away from this bonding pair until, in the limit, this electron pair may be regarded as the property of the anion alone. Then the positive ion, which is the nucleus M is held to symmetrical anion ${:}\ddot{\underset{..}{X}}{:}$ only by the fact that they are oppositely charged. When an electrolyte in a strongly polar or electrophilic medium approximates this condition it may be classified as a strong electrolyte.

Polarity.—The property of solutions of forming electrolytic conductors is associated with a classification which may be drawn between compounds according to whether they may be regarded as polar or non-polar. The distinction between these two classes is one of degree only and not of type, and depends not only on the constitution of the compound but on the medium in which it is dissolved. In comparison with non-polar compounds, the polar compounds are characterized by possessing a high degree of ionization or a good ionizing power as solvents, high dielectric constants, power of association, tautomerism, being electrophilic and forming molecular complexes.

Polarity of a molecule arises from the fact that in a molecular structure formed by interchange of electrons, although the charge of the nucleus is balanced by the surrounding electrons, yet on account of the unsymmetrical structure of the molecule the centre of the positive charges does not necessarily coincide with that of the negative ones, so that the molecule has a definite electric

moment. There is thus a stray field of force around the molecule and a bipole is formed, one side of the molecule being more positive or negative than the other. The molecule will thus attract and be attracted by other molecules. If the molecules of solvent possess a similar property, the negative side of one molecule will be attracted by the positive side of another and a definite electrostatic attraction exhibited which is shown as residual valency. When displacement of an electron occurs, and the charged parts of the molecule are separated by an appreciable distance, a bipole (or multi pole) of high electric moment is obtained and its force of attraction for another molecular bipole will be felt over a considerable intervening distance.

The part played by the solvent in dissociation is shown in that a bipole of small molecular moment which would scarcely attract a similar molecule, will be very appreciably attracted by a polar molecule or bipole of high moment and may form with it a double molecule. In general, if two molecules combine or even approach one another, each weakens the constraints which hold together the charge of the other, and the electrical moment of each is increased. This effect is cumulative in that, when two molecules by their approach or combination become more polar they draw other molecules more strongly towards them and this increases still further their polar character. The polar character of a substance thus depends not only upon the specific properties of the individual molecules but also upon what may be termed the strength of the polar environment.

According to the octet theory of valency, strong bases such as potassium hydroxide, barium hydroxide and all typical salts are to be regarded as completely ionized even in the solid condition. In the hydrochloric acid molecule the properties may be explained by regarding the hydrogen nucleus as sharing a pair of electrons with the chlorine atom. Anhydrous liquid hydrogen chloride is, therefore, a non-conductor of electricity since there are no free ions. In contact with water, however, separation of the molecule into ions occurs, which may be explained either from a consideration of the dielectric effect of the solvent, or else by regarding the hydrogen nucleus as attaching itself more easily to the unshared pairs of electrons in the octets of the water molecules than to the chlorine atoms, since the nuclei of the oxygen atoms have smaller positive charges than those of the chlorine atoms. The result is that the hydrogen nuclei become hydrated hydrogen ions, and the chlorine ions remain in solution. With a weak acid such as hydrogen sulphide, the tendency for the hydrogen nucleus to separate from the octet is very much less, which may be explained by the smaller positive charge on the nucleus of the sulphur atom causing the hydrogen nucleus to be much more firmly held. From this viewpoint, acids are thus to be regarded as substances from whose molecules hydrogen nuclei are readily abstracted, while bases are substances whose molecules can easily take up hydrogen nuclei.

Dielectric Constant.—The difference between polar or highly-ionized and non-polar or slightly ionized compounds is reflected in the dielectric constant which measures the number of free charges in the substance multiplied by the average distance through which these charges move under the influence of a definite electric field. It was enunciated by J. J. Thomson and independently by Nernst in 1893 that the ionizing power of a solvent is closely connected with its dielectric constant. This effect follows from Coulomb's law in which $f = \frac{1}{D} \frac{e_1 e_2}{l^2}$ where f represents the attracting or repelling force of unlike or like charges of electricity, e_1 and e_2 the electric charges which are separated by the distance l and D the dielectric constant.

In a detailed investigation made by Walden (*Z. Physik. Chem.*, 1903, 1906) the dissociating power of a very large number of organic liquids for the solute tetra ethyl ammonium iodide was measured, and it was found that a close parallelism exists between the dielectric constant of the solvent and the percentage dissociation of the solute. An empirical relation which was found to apply is given by the equation $D \sqrt[3]{\frac{1}{c}} =$ constant where c is the concentration at which the degree of ionization of the solute has a definite value in any solvent. It was found by Walden that the value of the dielectric constant of liquids is determined by certain groups. By the substitution of the following groups the magnitude of the increase of dielectric constant becomes greater in the following order:—

I, Br, Cl, F, NH_2, CN, CO_2H, CHO, CO, NO_2, OH.

According to the theory of Debye and Huckel the magnitude of inter-ionic effects is proportional to $D^{-\frac{3}{2}}$ as shown in equation (18a), and consequently should be most marked in solvents of low dielectric constant. The solvent cyclohexanol, for instance, has a dielectric constant of 15, so that $1-\phi$ and $-ln\ f$ should be $(88/15)^{-\frac{3}{2}} = 14{\cdot}2$ times greater than in water. Lithium salts are sufficiently soluble in cyclohexanol to determine the freezing-point depression, and the molar freezing-point constant (38·3°C) is twenty times that of water (1·86°). The results obtained are in close agreement with those required by the theory.

Voltaic Cells.—When two metallic conductors are placed in an electrolyte a current will flow through a wire connecting them, provided that a difference of any kind exists between the two conductors in the nature either of the metals or of the portions of the electrolyte which surround them. A current can be obtained by the combination of two metals in the same electrolyte, of two metals in different electrolytes, of the same metal in different electrolytes or of the same metal in solutions of the same electrolyte at different concentrations. In accordance with the principles of energetics (*q.v.*), any change which involves a decrease in the total available energy of the system will tend to occur, and thus the necessary and sufficient condition for the production of electromotive force is that the available energy of the system should decrease when the current flows.

In order that the current should be maintained and the electromotive force of the cell remain constant during action, it is necessary to ensure that the changes in the cell, chemical or other, which produce the current should neither destroy the difference between the electrodes, nor coat either electrode with a non-conducting layer through which the current cannot pass. As an example of a fairly constant cell we may take that of Daniell, which consists of the electrical arrangement—zinc | zinc sulphate solution | copper sulphate solution | copper—the two solutions being usually separated by a pot of porous earthenware. When the zinc and copper plates are connected through a wire a current flows, the conventionally positive electricity passing from copper to zinc in the wire and from zinc to copper in the cell. Zinc dissolves at the anode, an equal amount of zinc replaces an equivalent amount of copper on the other side of the porous partition, and the same amount of copper is deposited on the cathode.

It is necessary to observe that the condition for change in a system is that the total available energy of the whole system should be decreased by the change. Thus in the Daniell cell the dissolution of copper as well as of zinc would increase the loss in available energy. But when zinc dissolves, the zinc ions carry their electric charges with them, and the liquid tends to become positively electrified. The electric forces then soon stop further action unless an equivalent quantity of positive ions are removed from the solution. Hence zinc can only dissolve when some more easily separable substance is present in solution to be removed *pari passu* with the dissolution of zinc. The mechanism of such systems is well illustrated by an experiment devised by W. Ostwald. Plates of platinum and pure or amalgamated zinc are separated by a porous pot, and each surrounded by some of the same solution of a salt of a metal more oxidizable than zinc, such as potassium. When the plates are connected together by means of a wire no current flows and no appreciable amount of zinc dissolves, for the dissolution of zinc would involve the separation of potassium and a gain in available energy. If sulphuric acid be added to the vessel containing the zinc, these conditions are unaltered and still no zinc is dissolved. But on the other hand if a few drops of acid be placed in the vessel with the platinum, bubbles of hydrogen appear and a current flows, zinc dissolving at the anode, and hydrogen being liberated at the cathode. In order that positively electrified ions may enter a solution, an equivalent

amount of other positive ions must be removed or negative ions be added, and for the process to occur spontaneously the possible action at the two electrodes must involve a decrease in the total available energy of the system.

Concentration Cells.—As stated above, an electromotive force is set up whenever there is a difference of any kind at two electrodes immersed in electrolytes. In ordinary cells the difference is secured by using two dissimilar metals, but an electromotive force exists if two plates of the same metal are placed in solutions of different substances or of the same substance at different concentrations. In the latter case the tendency of the metal to dissolve in the more dilute solution is greater than its tendency to dissolve in the more concentrated solution, and thus there is a decrease in available energy when metal dissolves in the dilute solution and separates in equivalent quantity from the concentrated solution. An electromotive force is therefore set up in this direction, and if we can calculate the change in available energy due to the processes of the cell we can foretell the value of the electromotive force. Now the effective change produced by the action of the current is the concentration of the more dilute solution by the dissolution of metal in it, and the dilution of the originally stronger solution by the separation of metal from it. We may imagine these changes reversed in two ways. We may evaporate some of the solvent from the solution which has become weaker, and thus reconcentrate it, condensing the vapour on the solution which had become stronger. By this reasoning Helmholtz showed how to obtain an expression for the work done. On the other hand we may imagine the processes due to the electrical transfer to be reversed by an osmotic operation. Solvent may be supposed to be squeezed out from the solution which has become more dilute through a semi-permeable wall, and through another such wall allowed to mix with the solution which in the electrical operation had become more concentrated. Again, we may calculate the osmotic work done, and if the whole cycle of operations be supposed to occur at the same temperature, the osmotic work must be equal and opposite to the electrical work of the first operation.

The result of the investigation shows that the electrical work Ee is given by the equation

$$Ee=\int_{p_1}^{p_2} v\,dp$$

where v is the volume of the solution used and p its osmotic pressure. When the solutions may be taken as effectively dilute, so that the gas laws apply to the osmotic pressure, this relation reduces to

$$E=\frac{n^{\nu}RT}{ey}\log_e\frac{c_1}{c_2}$$

where n is the number of ions given by one molecule of the salt, r the transport ratio of the anion, R the gas constant, T the absolute temperature, y the total valency of the anions obtained from one molecule, and c_1 and c_2 the concentrations of the two solutions. If we take as an example a concentration cell in which silver plates are placed in solutions of silver nitrate, one of which is ten times as strong as the other, this equation gives

$$E=0{\cdot}060\times10^8 \text{ c.g.s. units}$$
$$=0{\cdot}060 \text{ volts.}$$

W. Nernst, to whom this theory is due, determined the electromotive force of this cell experimentally, and found the value 0·055 volt.

The logarithmic formulae for these concentration cells indicate that, theoretically, their electromotive force can be increased to any extent by diminishing without limit the concentration of the more dilute solution, log c_1/c_2 then becoming very great. This condition may be realized to some extent in a manner that throws light on the general theory of the voltaic cell. Let us consider the arrangement—silver | silver chloride with potassium chloride solution | potassium nitrate solution | silver nitrate solution | silver. Silver chloride is a very insoluble substance, and here the amount in solution is still further reduced by the presence of excess of chlorine ions of the potassium salt. Thus silver, at one end of the cell in contact with many silver ions of the silver nitrate solution, at the other end is in contact with a liquid in which the concentration of those ions is very small indeed. The result is that a high electromotive force is set up, which has been calculated as 0·52 volt, and observed as 0·51 volt. Again, Hittorf has shown that the effect of a cyanide round a copper electrode is to combine with the copper ions. The concentration of the simple copper ions is then so much diminished that the copper plate becomes an anode with regard to zinc. Thus the cell—copper | potassium cyanide solution | potassium sulphate solution—zinc sulphate solution | zinc—gives a current which carries copper into solution and deposits zinc. In a similar way silver could be made to act as anode with respect to cadmium.

It is now evident that the electromotive force of an ordinary chemical cell such as that of Daniell depends on the concentration of the solutions as well as on the nature of the metals. In ordinary cases possible changes in the concentrations only affect the electromotive force by a few parts in a hundred, but by means such as those indicated above it is possible to produce such immense differences in the concentrations that the electromotive force of the cell is not only changed appreciably but even reversed in direction. Any reversible cell can theoretically be employed as an accumulator, though in practice conditions of general convenience are more sought after than thermodynamic efficiency (*see* ACCUMULATOR.) The reversibility of a cell is in general modified by the phenomenon of polarization (*see* ELECTRO-CHEMISTRY).

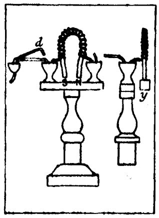
ELECTROMAGNET. Soon after the discovery, by Oersted in 1820, of the directive action of an electric current on a magnetic needle, it was found that a wire carrying an electric current also possessed the power of magnetizing pieces of steel and iron placed near it. This discovery was made by D. F. J. Arago (*Ann. de Chim. et de Physique*, 1820), who announced that a copper wire conveying an electric current could magnetize steel needles placed across it, and could attract iron filings. In October of the same year these facts were discovered independently by Sir Humphry Davy (*Phil. Trans. R. S.*, 1820). In one of Davy's experiments a number of steel needles were fastened to a silver wire in different directions, some being parallel and others transverse to the wire. When the ends of the wire were connected to a battery the needles parallel to the wire attracted iron filings in much the same way as did the wire itself, and they lost this power when the connection with the battery was broken. Each of the needles placed across the wire, however, acquired two magnetic poles, and retained its magnetism after the current was broken. Pieces of iron wire placed across the silver wire also became magnetized, and they lost their magnetism when the battery connection was broken. About the same time Arago and A. M. Ampère magnetized a steel needle which was wrapped in paper and placed within a helical coil of wire carrying a current.

It was a short but extremely important step from these preliminary discoveries to the production of the electromagnet, a combination of coil of wire and iron core which was destined to become one of the principal elements in the successful development of the technical applications of electricity. The step was taken by William Sturgeon, a native of Whittingham, in Lancashire, where he was born in 1783. He was a shoemaker by trade and for 18 years a private soldier in the Royal Artillery, entirely self-taught, but an enthusiastic experimenter in electricity. Sturgeon's electromagnet, front and side views of which are shown in fig. 1, was described by him in a communication to the Society of Arts in 1825 (*Trans. Society of Arts*, 1825). It consisted of

a bent bar of soft iron, about a foot long and half an inch in diameter, coated with varnish, on which was wound a coil of bare copper wire of 18 turns. The ends of the wire dipped into mercury cups, mounted on a wood stand, for leading in the electric current. When a current was passed through the wire the bar became a strong magnet, and could support a heavy iron mass applied to its ends, as at *y*, fig. 1. When the connection at *d* was broken, the weight immediately fell. The weight of the bent iron core of Sturgeon's electromagnet was 7 oz., and when excited by the current from a single cell it supported a weight of 9 lb. Sturgeon's experiments soon attracted the attention of other investigators, among them Joseph Henry in the United States, who in 1831 described an important improvement which he had effected (*Silliman's Journal*, 1831). Instead of insulating the iron bar he covered the wire with silk, and wound a great number of turns of it round the bar in the same direction. A horseshoe-shaped electro-magnet which he made in this way for Princeton lifted 750 lb. when excited by the current from a small battery, and another one, for Yale college, supported 2,086 lb. Henry also found that his electromagnets could be operated by a battery at a considerable distance, and actually succeed by this means in establishing an electromagnetic telegraph in 1831.



BY COURTESY OF ROYAL SOCIETY OF ARTS FROM THE "TRANSACTIONS OF THE SOCIETY"

FIG. 1.—FRONT AND SIDE VIEWS OF STURGEON'S ELECTROMAGNET, THE FIRST TO BE INVENTED (1825)

In 1838 Sturgeon removed to Manchester, where he came into contact with J. P. Joule, who afterwards became famed for his researches on the equivalence of heat and mechanical work. During the two following years Joule devoted much attention to the study of the lifting power of electromagnets. One form which he constructed consisted of a thick-walled tube of wrought iron, cut longitudinally into two unequal parts. The larger part was wound longitudinally with insulated copper wire, and the smaller part acted as keeper. This electromagnet, the iron of which weighed 15 lb., was found to be capable of supporting a weight of 2,090 lb. In another form of lifting magnet designed by Joule, a number of flat pieces of iron were bolted to one side of a strong brass ring, and had rectangular grooves cut in them of width equal to the spaces between them. A bundle of insulated copper wires was bent to and fro in the grooves and the spaces. A similar set of pieces of iron, but without grooves, was bolted to another brass ring, and applied to the first set, as armature, so that the grooves in the first covered the spaces in the second. A "zigzag ring of iron" was thus formed, and with the current from 16 cells a weight of 2,710 lb. was supported, the weight of the iron pieces being in all 11·575 lb. (*See* Joule's *Scientific Papers* published by the Physical Society of London.)

Lifting magnets are now much used for lifting steel ingots, tubes, girders, scrap iron, etc., and for handling metal when it is at a high temperature. They are also made watertight so that they can operate under water. Modern lifting magnets are usually of the bell or mushroom form, the magnetizing coil being placed round the central core, and the poles being therefore at the centre and the rim. In fig. 2 is shown a lifting magnet in operation, and the steam engine and dynamo for generating the current supplied to the magnet. A magnet of this type, 66in. in diameter, and weighing nearly 3 tons, can support ten times its weight of iron.

Owing to the great normal pressure between strongly magnetized surfaces in contact, a large amount of friction may be called into play, and this force, which is easily controllable, is put to practical use in electromagnetic clutches, chucks and brakes. Electromagnets are also used, for a great variety of purposes, in producing movement at a distance from the operator, as in electric bells, telephone receivers and wireless loud speakers. The electromagnet provides, in fact, by far the most convenient means of producing such effects. Probably the most important practical applications of the electromagnet, however, are found in the dynamo and the electric motor, where it is used for producing the electric field in which the armature rotates, and in the transformer, where a varying field is caused to induce current in a secondary circuit.

In addition to its practical uses, the electromagnet has also played a part in several important scientific discoveries. It was used by Faraday in his discovery of the rotation of the plane of polarization of light in a magnetic field, and other investigations in magnetism. One of Faraday's electromagnets is still preserved at the Royal Institution. The Kerr magnetic effect, a rotation of the plane of polarization of light reflected from the polished pole piece of a magnet, was discovered by Dr. John Kerr with an electromagnet now in the Natural Philosophy department of the University of Glasgow. An electromagnet was also used by Zeeman in his great discovery of the effect now known by his name, a splitting of the spectral lines of a source of light placed in a magnetic field. The practical and scientific applications of electromagnets are almost innumerable. All we can here attempt is to make a broad classification of them, and to give an outline of the principles underlying the action of electromagnets, and the design of electromagnets for the various purposes which they are intended to serve.

The Magnetic Circuit.—Every electromagnet includes an electric circuit linked with a magnetic circuit in which there is a certain amount of magnetic flux, or number of tubes of magnetic induction. The relation between the electric current and the magnetic flux is expressed by the equation of the magnetic circuit, which is based upon the two fundamental principles:—(1) The line integral of the magnetic force H taken round any closed curve, known as the magnetomotive force in the curve, is equal to $4\pi ni$, where n is the number of turns of wire linked with the curve, and i is the current in the wire in c.g.s. units. (2) Just as the electric current is the same in all parts of the electric circuit, so the total magnetic flux is the same in all parts of the magnetic circuit.

The relation between the magnetomotive force and the flux in a magnetic circuit is expressed in terms of a quantity known as the magnetic reluctance of the circuit. This quantity depends upon the dimensions of the circuit and upon the magnetic quality of the materials of which it is composed. Its value may be derived in the following manner. In any portion of the circuit of mean length l and cross section S, let the mean value of the magnetic force be H, and let N denote the total flux. Then the mean value of the flux density, or magnetic induction, B, is N/S, and from the definition of magnetic permeability μ $H=B/\mu=N/\mu S$, and therefore $Hl=Nl/\mu S$. Forming similar equations for the other portions of the circuit and adding them together, bearing in mind that N is the same in all parts of the circuit, we have, on the left-hand side of the resulting equation, the magnetomotive force in the circuit, and, on the right hand side, the product of the flux and the sum of the quotients $l/\mu S$ for all parts of the circuit. This sum is what is known as the magnetic reluctance of the circuit. It may also be expressed as the sum of the quantities $l\rho/S$ for all parts of the circuit, where ρ is the reluctivity of the material, *i.e.*, the reciprocal of the permeability.

FIG. 2.—LIFTING MAGNET, "MUSHROOM" FORM, CAPABLE OF SUPPORTING TEN TIMES ITS OWN WEIGHT OF IRON. THE DYNAMO FOR GENERATING THE CURRENT IS DRIVEN BY A STEAM ENGINE

If the current is expressed in amperes, the magnetomotive force is $4\pi ni/10$, or $1{\cdot}257ni$. Thus the equation of the magnetic circuit is $1{\cdot}257 \times$ampere-turns $(ni)=N\times$magnetic reluctance. This equation is analogous to that which expresses Ohm's law for an electric circuit; viz., electromotive force=current$\times$resistance. An important difference between the electric circuit and the mag-

netic circuit arises from the fact that, whereas the electric resistance of a solid or liquid conductor is independent of the current so long as the temperature and other physical conditions are constant, the magnetic reluctance varies with the magnetic flux, and for its determination a knowledge of the permeability of the materials at different flux densities is required. From the permeability curves of the materials the magnetic reluctance of each portion of the magnetic circuit can be calculated, and hence the ampere-turns required to produce a given flux in the circuit.

As an example, suppose that a ring of iron has a mean diameter of 10cm. and a cross section of 2sq.cm., and a transverse cut or air gap made in it 1mm. wide. Let us inquire the ampere-turns required on the ring to create in it a total flux of 24,000 c.g.s. units. The length of the iron part of the circuit is $10\pi - 0{\cdot}1$cm., and as its section is 2sq.cm., the flux density in it is 12,000 c.g.s. units. Assuming that the permeability of pure iron at this flux density is 2,760, we find that the reluctance of the iron portion of the circuit is $(10\pi - 0{\cdot}1)/2 \times 2{,}760$, or about 0·0057 c.g.s. unit. The length of the air gap is 0·1cm., its section 2sq.cm., and its permeability unity. Hence the reluctance of the air gap is $0{\cdot}1/2 = 0{\cdot}05$ c.g.s. Consequently the number of ampere-turns required to produce the flux is $ni = \frac{24{,}000}{1{\cdot}257}(0{\cdot}0057 + 0{\cdot}05) = 1060$ (nearly).

We may therefore say that the part of the magnetomotive force required to overcome the reluctance of the air gap is about nine times that required for the iron alone. In reality, when there is an air gap in a magnetic circuit, the flux does not all pass straight across it, as we have assumed in the above example, but it spreads out beyond the edge of the gap. The flux within the gap is less than the mean flux in the iron. If it were required to produce a certain flux in the air gap, extra ampere-turns would be necessary to allow for this spreading. The correction in such cases is determined by the use of what are called leakage co-efficients, *i.e.*, numbers representing the ratio of the mean flux in the iron portion of the circuit to the flux in the gap. The practical application of the principle of the magnetic circuit to the predetermination of the field windings of dynamo magnets was first made by J. and E. Hopkinson (*Phil. Trans.*, 1886). (*See* ELECTRIC GENERATOR.)

Iron and Steel for Electromagnets.—There are many methods for determining the permeability of magnetic materials at various values of the flux density, for an account of which reference may be made to the article MAGNETISM. In Table I. are given values of *B* and *H*, found by Ewing by the ballistic method, for two magnetic materials which are used in the construction of electromagnets (*Proc. Inst. C.E.*, 1896). The figures under heading (*a*) refer to a sample of forged ingot iron for dynamo magnets, those under (*b*) to an unforged steel casting made by the Siemens process. The values of the magnetizing force *H*, and the flux density *B*, are given in c.g.s. units.

TABLE I.

The metal of which the tests are given in Table II. contained 2% of silicon, 2·85% of total carbon, and 0·5% of manganese. In fig. 3 the flux density and the permeability for other typical samples of commercial iron and steel for electromagnets (from data in Miles Walker, *Specification and Design of Dynamo Electric Machinery*, 1918), are shown in the form of curves. Curve I. is the magnetization curve, or (*B*, *H*) curve of a sample of cast-iron. Curve II. is the magnetization curve of an annealed steel casting, unforged, containing 0·2% of carbon. Curve II.*a* shows the permeability (upper horizontal scale) of this material for various values of *B* shown on the vertical scale. Curves III. and III.*a* are the magnetization and permeability curves for an annealed sample of forged ingot iron. Curves IV. and IV.*a* similarly show the magnetic properties of a sample of silicon steel containing 4·8% of silicon and 0·2% of carbon. Ingot iron is probably the purest iron which can be obtained commercially in large quantities. The sample the magnetic properties of which are shown in curves III. and III.*a*, fig. 3, contained 0·15% of carbon, but in some samples the total foreign matter, including carbon, manganese, sulphur, does not amount to this percentage of the whole. Owing to its relatively high permeability at all values of the flux density, this material is very suitable for the cores of dynamo magnets. It is, however, not very suitable for electromagnets supplied with alternating currents, owing to its low specific resistance, or resistivity, and the consequent losses in it due to eddy currents. The maximum permeability of the specimen represented in curves III. and III.*a*, fig. 3, is 2,320 at the flux density $B = 10{,}000$ c.g.s.

Magnet cores of cast steel (mild steel) are less costly than those of forged metal, and, as shown in the foregoing tables and curves, mild steel is little inferior to the latter in its magnetic quality. Steel castings are therefore much used for the cores and yokes of dynamo magnets. As indicated in Table II. and curve I, fig. 3, the magnetic properties of cast iron are much inferior to those of the low-carbon steels. Cast iron is, however, used for the yokes and frames of dynamo machines, being easily cast and inexpensive, but it is less used now than it was formerly.

It was discovered in 1903 by Sir Robert Hadfield that certain iron-silicon alloys have very high permeability at low values of the flux density. This property is illustrated by curves IV. and IV.*a* in fig 3, the maximum permeability for the specimen represented being 3,790 at the induction 8,000 c.g.s. In stronger fields, however, the presence of the silicon lowers the permeability. Silicon steel is not suitable for the cores of electromagnets in which high flux density is required, but, owing to the comparatively small dissipation of energy in this material when the flux is alternating, it is largely used in the form of thin sheet for the cores of alternate current transformers. The best qualities of silicon steel contain 3·5 to 4·5% of silicon, and practically no other foreign matter. With much larger proportions of silicon the material tends to become brittle, and the permeability in strong fields is further diminished. With smaller proportions of silicon this material is also used for the armatures of dynamos, but for this purpose stampings of dynamo sheet-steel, containing less than 1% of silicon are more suitable, owing to the higher permeability of this material at high flux densities.

FIG. 3.—MAGNETIZATION CURVES
Curves showing flux-density and permeability for different irons and steels used in the construction of electromagnets

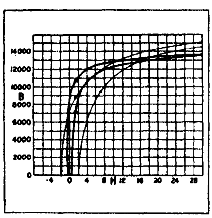
When sheet-steel is used in electro-magnets it should be placed so that as far as possible the direction of magnetization is parallel to the grain, *i.e.*, the direction in which the sheet has been rolled. The magnetic properties in a direction at right-angles to the grain are usually inferior to those in the grain direction. The maximum permeability of a material may be considerably increased by careful re-annealing. Values as high as 12,000 have been found by

Gumlich in iron-silicon alloys as the result of this treatment. The effect of preparing and annealing iron and iron-silicon alloys *in vacuo* has been studied by Yensen (*Proc. Am. I.E.E.*, 1915, 1916), who found great increase in the maximum permeability, the effect being due to a reduction in the impurities, especially carbon.

The remarkable magnetic properties of two other alloys may be referred to briefly. The material known as "permalloy," a very pure nickel-iron alloy containing about 78·5% of nickel, shows very high permeability in weak magnetizing fields. Under a magnetic force of $\frac{1}{20}$ c.g.s. unit the induction in permalloy may be as great as 5,000 c.g.s units the permeability being therefore 100,000. If a straight copper wire of diameter 1mm., carrying a current of 1/800 ampere, were closely surrounded by a sheath of permalloy, the induction in the innermost layer of the sheath might be about 5,000 c.g.s. The self-inductance of the wire would thus be greatly increased. It is for "loading" a wire in this way that permalloy is at present chiefly useful in connection with telegraph and telephone cables. In strong fields the permeability of permalloy is inferior to that of good cast iron. A very different property is possessed by the cobalt-iron alloy containing about 34·5% of cobalt. This alloy was shown by P. Weiss to have remarkably high magnetization in strong fields, the saturation induction $B-H$ being about 12% higher than that of pure iron. This material is very suitable for the pole-pieces of electromagnets used in producing very intense magnetic fields.

Core Losses.—In iron or other magnetic material in which the flux is rapidly alternating there are two sources of dissipation of energy which it is desirable to reduce as much as possible, viz., hysteresis and eddy currents. Hysteresis is the name given by Ewing to that property of magnetic materials which causes the flux density, at any change from increasing to diminishing magnetization or vice versa, to follow a different path in relation to the magnetizing force. The induction "lags behind" the force at such changes. The practical importance of hysteresis lies in the fact that, as shown by E. Warburg and Ewing, in any cyclic process of magnetization, there is energy dissipated, the amount of which is proportional to the area of the corresponding "hysteresis loop." In transformer cores, which are subject to rapid alternations of magnetization, the hysteresis loss per second, being proportional to the rate of alternation, may become serious. It is, therefore, important that the material of the cores should be chosen so that the area of the loop corresponding to the range of induction employed should be as small as possible.

Much attention has been devoted to the study of the hysteresis loss as affected by the maximum flux density in the cycle and by the nature and state of the material, and various practical methods of measuring hysteresis have been devised. The results may be expressed in ergs per cycle per cubic centimetre of the material, or in watts per pound at some stated frequency of alternation and at some maximum flux density, say, at 50 cycles per second and 10,000 c.g.s units of flux density. The relative qualities in regard to hysteresis of two kinds of sheet-steel are illustrated in fig. 4, which shows the upper portions of their hysteresis loops as determined by H. Hoffmann (*Arch. f. Elektrot.*, 1913). The full line curve refers to an annealed specimen of silicon steel, the broken line curve to a sample of ordinary sheet steel. The superiority of the silicon steel is shown by the relative smallness of the area of its hysteresis loop, and the consequent low value of the hysteresis loss in this material. Silicon steel of good quality is also practically free from the defect known as "ageing," *i.e.*, the increase in the hysteresis loss which occurs in ordinary iron or steel when subjected for prolonged periods to temperatures in the neighbourhood of 100° C.



FROM "DICTIONARY OF APPLIED PHYSICS"

FIG. 4.—HYSTERESIS CURVES
"B–H" curves showing comparative hysteresis of an annealed silicon steel (thick line), and of an ordinary sheet steel (thin line)

Various empirical formulae have been proposed to express the hysteresis loss in terms of the maximum flux density in the cycle. The best known of these is that of Steinmetz, which represents the hysteresis loss by the expression $hB^{1.6}$, h being a constant. The value of h is very small in the iron-silicon alloys (*see* MAGNETISM). For the specimen represented by the full-line curve in fig. 4 the value of h was 0·001, when the hysteresis loss is expressed in ergs per cycle per cubic centimetre. For the sample of ordinary sheet-steel represented in fig. 4 the value of h was 0·0024. In a very pure annealed specimen of alloyed steel 0·5mm. thick, containing 4·09% of silicon and 0·07% of carbon, Gumlich found the value 0·0006 for h.

The other core loss in alternating current cores (often more than one half of the total core loss) arises from the eddy currents induced in the cores by the changes of flux, and it is for the purpose of reducing this loss that the cores of alternating current electromagnets are made of thin sheets of material, insulated from one another, and so disposed that their planes are parallel to the direction of the flux. The theory of eddy-currents in laminated cores was given by J. J. Thomson (*Electrician*, 1892), who showed that the energy dissipated owing to this cause per second per cubic centimetre of the material is proportional, when the quantity $\pi d\sqrt{n\mu\sigma}$ is small, to $d^2n^2B^2/\sigma$, where d is the thickness of each sheet, n is the frequency of alternation, B the maximum induction, and σ the specific resistance of the material. In low-frequency alternations therefore the eddy-current loss diminishes as the specific resistance of the material increases. The specific resistance of alloyed steel may be five or six times as great as that of ordinary steel sheet, and the eddy-current loss is therefore smaller in the former material. This is another reason why silicon steel is a superior material to ordinary sheet-steel for transformer and other alternating current cores. (*See* TRANSFORMERS.) It will be noted that the eddy-current loss per second is proportional to the square of the frequency, and this fact forms the basis of one of the chief methods of separating the eddy-current loss from the hysteresis loss, the latter being proportional to the frequency. In commercial silicon steel plates of good quality 0·5mm. thick, at a maximum induction of 10,000 c.g.s. units and frequency 50 per second, the combined hysteresis and eddy-current losses amount to less than 1 watt per pound of the material.

Electromagnets for Producing Intense Magnetic Fields.—The problem of producing a very intense magnetic field in a small air gap in a magnetic circuit is very different from that of producing a large amount of total flux in the armature of a dynamo. In the latter case great concentration of the flux is not desired. The flux density in the air gaps separating the pole-pieces from the armature of a dynamo does not usually exceed about 15,000c.g.s. units, but in electromagnets used for the purpose of examining the magnetic properties of iron and other magnetic materials in very strong fields, and for many physical experiments, a much greater degree of concentration of the flux is required.

The magnetic field in the air gap may be regarded as made up of two parts; viz., that due to the magnetic poles on the sides of the gap, and that due directly to the magnetic action of the current in the magnetizing coils. Unless this current is extremely strong the magnetic field which it produces in the gap is very small in comparison with that due to the magnetism on the pole-faces. We conclude, therefore, that, if the pole-faces are parallel planes extending across the whole cross section of the core, the magnetic field in the gap between them cannot much exceed the saturation flux density of the iron, which is about 21,600 c.g.s. units. It is clear that, in the case of the gap with plane parallel sides, the poles near the periphery of the gap do not contribute much to the magnetic field at the centre. They might be expected to contribute more if they were laid back, away from the gap, so that they could produce greater magnetic force in the axial direction at the centre of the gap. This is found to be the case experimentally, and conical pole-pieces, having surfaces in the form of truncated cones, are generally used in electromagnets for producing very intense fields. The angles which the cones

should have in order to produce the most concentrated field was calculated by Stefan and by Ewing in 1888 on the assumption that the pole-pieces are uniformly magnetized to saturation in the axial direction. The calculation showed that the pole-faces should take the form of cones of semi-vertical angle 54° 44′, and that with this angle the value of the field at the vertex of the cones is given by the expression $0{\cdot}886(B\text{–}H)\ \log_{10}\frac{b}{a}$ where b is the radius of the base of the cones, and a is the radius of the cone at the narrow end, *i.e.*, the radius of the gap. Assuming the saturation value 21,600 for $B\text{–}H$ this gives $19{,}140\ \log_{10}\frac{b}{a}$ as the maximum field strength produced by conical pole-faces. To this must be added the field due to the magnetism on the narrow plane ends of the cones (unless the gap is bridged across by a narrow neck or "isthmus"), and the field due to the magnet coils. In practice the angle of the cores for maximum concentration should, as pointed out by Ewing, be rather greater than 54° 44′, owing to the fact that the magnetization of the pole-pieces is not quite uniform. The question of the best form of pole-piece was examined experimentally by du Bois, who found that for maximum concentration the angle should also increase slightly towards the base of the cone. The coils should be placed on the electromagnet so as to produce, by the direct action of the current, the greatest possible field in the gap, that is, their end windings should be as near the gap as possible. In this position the coils will also have their greatest effect in saturating the pole-pieces.

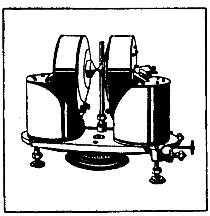
In 1891 du Bois designed a large electromagnet in which the core was a ring of Swedish iron of mean diameter 50cm. and diameter of section 10cm. The coils contained 2,400 turns of wire which could carry 50 amperes. The weight of this electromagnet was about 5cwt. With conical pole-pieces the electromagnet gave a maximum field of 40,000c.g.s. units (or gauss) in a gap 1mm. wide and 6mm. in diameter. Subsequently du Bois designed a more convenient form of electromagnet, known as the half-ring type, which is now much used in experimental and testing work. The latest type of du Bois half-ring electromagnet is illustrated in fig. 5 (from the *Zeitschrift fur Instrumentenkunde,* 1911), where it is shown mounted on a turn-table so that it can be rotated easily about a vertical axis. In this type each of the two curved cores of cast-steel forms about one-third of a complete ring, the diameter of the core section increasing towards the base. The form of the coils is such as to allow optical or other apparatus to be brought close up to the borings in the cores, and extra polar coils are provided which can be slipped over the pole-pieces so as to be in the most effective position for increasing the field. A copper tube also surrounds the upper end of each core, to carry a current of water for cooling. This electromagnet is made in several sizes. In one model, weighing 7cwt., the maximum field in a gap 1mm. wide and 6mm. diameter is 50,000 gauss. With a smaller gap of 0·5×3mm. and with ferro-cobalt pole-tips the field is 59,000 gauss. A larger model weighing 27cwt. and having cores 20cm. in diameter at the upper end, gives in the 0·5×3mm. gap a field of 65,000 gauss.

Very powerful electromagnets have also been designed by P. Weiss (*Journ. de Phys.,* 1907) who has adopted and improved upon the well known Ruhmkorff pattern. In this type the coils are carried by two horizontal coaxial cores supported by a massive yoke. In the Weiss electromagnets very adequate arrangements are made for cooling the coils, one method being to immerse the windings in oil cooled by water circulating in a spiral tube. A magnet of this type weighing 25½cwt., excited by a current of 60 amperes, gave a field of 46,000 gauss in a 2×6mm. gap. In a later and still larger model (*Arch. des Sciences,* 1917) the current of 100 amperes is carried by 1,440 turns of copper tubing which also conveys the current of cooling water. The ten sections into which the coils are divided are connected in series for the electric current, and in parallel for the current of cooling water. A very large electromagnet of this type has recently been completed at Paris, where it is installed at the Office of Research and Inventions. It is said to have cores over one metre in diameter at the base, to be wound with 5,000 metres of copper tube and to weigh over 100 tons.

The general effect of increase of dimensions of an electromagnet on the field which it produces may be gathered from the principle of similarity, stated by Lord Kelvin, which may be expressed as follows:—If the linear dimensions of an electromagnet are increased in any ratio, and if the current in the coils is increased in the same ratio, the flux density at corresponding points will be unaltered. If, for example, the linear dimensions of an electromagnet were all doubled, and the current also doubled, the field intensity in the gap would be the same as before. The linear dimensions of the gap between the pole-tips would, however, be twice as great as before, and if the gap were reduced to its former size there would be an increase of field intensity equal to about $19{,}140\ \log_{10}2$, that is about 5,740 gauss, assuming the pole-pieces to be saturated. It is clear therefore that no very great increment of field intensity can be expected as the result of any reasonable increase in the dimensions of a large electromagnet of the ordinary type, in which the field is mainly due to the magnetism of the pole-pieces. There remains, however, the possibility of increasing the current in the magnet coils so greatly that the field due directly to the current becomes a large fraction of the total field.

This procedure was adopted in 1914 by Deslandres and Perot (*Comptes Rendus,* 1914) who, with a current of 5,000 amperes flowing in a water-cooled spiral of silver ribbon, and without an iron core, produced a field intensity of 49,900 gauss. When the spiral was provided with an iron core a field intensity of 63,700 c.g.s. units was attained. The method of producing intense magnetic fields by means of very strong currents has been much developed, at Cambridge, by P. Kapitza (*Proc. Roy. Soc.,* A, 1924). In his earlier experiments Kapitza, using specially constructed accumulator batteries and switch gear, passed currents up to 8,000 amperes (measured by a shunted oscillograph) through a coil for short intervals of time. In a coil of 1mm. internal diameter, fields of the order 500,000 gauss for 0·003 second were obtained in this way. In his later experiments (*ibid.,* 1927) still stronger currents were produced by short-circuiting an alternating current generator of special construction, and a field of 320,000 gauss in a volume of 2cu.cm. was obtained for ·01 second.

Mechanical Forces Produced by Electromagnets.—Electromagnets are used in different ways for exerting mechanical force on bodies placed near them. The force causing a bar of iron to adhere to the poles of a horseshoe magnet, known as the *tractive force* of the magnet, follows a different law from that of the force acting on a small magnetic body placed in the field of a magnet. In another class of applications, the most important example of which is found in the electric motor (*see* MOTORS, ELECTRIC), the field of an electromagnet is used for exerting force upon a wire in which a current of electricity is flowing. The law of the tractive force of electromagnets, first announced correctly by Clerk Maxwell, states that the normal traction between two plane pole-faces, placed in contact and magnetized uniformly in a direction at right angles to their common interface, is equal to $B^2A/8\pi$ where B is the flux density and A is the area of the surface of contact. The expression $B^2A/8\pi$ represents the total normal traction exerted across the area A, and in some cases this may be considerably greater than the force required to pull the surfaces apart. For example, if two iron bars of cross section A are passed through the borings of the electromagnet depicted in fig. 5, and placed so that the plane of contact of their ends is midway between the pole-pieces, the force required to separate



FROM H. DU BOIS, "NEUE HALBRING-ELEKTROMAGNETE"

FIG. 5.—THE DU BOIS ELECTROMAGNET, WHICH IS MOUNTED ON A TURN-TABLE, AND CAN BE EASILY ROTATED ABOUT A VERTICAL AXIS

the bars is approximately $(B^2-H^2)A/8\pi$, the difference $H^2A/8\pi$ representing a portion of the attraction between the pole-pieces, which is of course not overcome when the bars are pulled apart. In an experiment conducted on these lines with the du Bois ring electromagnet, the area of the cross section of the bar was 0·1896 sq.cm., the value of B was 39,260, and that of H was 17,690 c.g.s units. The value of $B^2A/8\pi$ was 11·86, that of $H^2A/8\pi$ was 2·386, both expressed in kilogrammes weight. Thus $(B^2-H^2)A/8\pi$ was 9·474, which agrees well with the observed pull which was 9·43kg. weight. In another experiment the pull between the bars was 1,634lb. weight per square inch of their cross section.

In ordinary cases, such as that of a horseshoe or mushroom-shaped electromagnet supporting an iron mass attached to its poles, the lifting force is represented by $B^2/8\pi$ per unit area of contact surface, and both poles are of course to be taken into account. From this expression we can find the effect of a change of dimensions of a lifting magnet, with proportional change of current and consequently no change of flux density, on the lifting power. Since the weight which it can support is proportional to the area of the contact surfaces, that is, to the square of the linear dimensions, while the weight of the magnet itself is proportional to their cube, it follows that the ratio of the lifting power of a magnet to the weight of the magnet itself is inversely proportional to the linear dimensions. Thus, in proportion to their weight, small magnets can lift more than large ones. One of Joule's electromagnets weighed only half a grain and it could support 1,417 grains, or 2,834 times its own weight.

Turning now to the question of the force acting on a small magnetized body placed in a magnetic field, we find in the first place that if the field is uniform there is no resultant force on the body since its two poles are subjected to equal and opposite forces. The resultant force on the body must therefore depend upon the non-uniformity of the field. It acts in the direction in which the spatial variation of the field is greatest, urging magnetic bodies towards the stronger, and diamagnetic bodies towards the weaker parts of the field. (*See* MAGNETISM.)

The force here considered has been put to practical use in the surgical electromagnets used for extracting small particles of iron or steel from the eye or other parts of the body. The same forces are employed in magnetic separators used for separating iron from other materials. In one machine the electromagnet is formed by the separator pulley, which contains a number of coaxial coils, the windings of which are near the curved surface of the pulley. The coils are separated from one another by steel discs, the rims of which, lying in the surface of the pulley, form the poles. The diagram in fig. 6 shows the mode of action of the separator pulley. The particles of magnetic material adhere to the belt where it is in contact with the pulley, but leave it after contact with the pulley is broken.

The force due to non-uniformity of the field is also used in certain scientific experiments, for example, in the determination of the magnetic susceptibility of weakly magnetic substances by Curie's method, and in the experiments of Gerlach and Stern for measuring the magnetic moments of atoms. (*See* MAGNETISM.)

Electromagnetic Mechanisms.—There have been invented a very large number of devices in which there is a small movement of a piece of iron forming part of the magnetic circuit of an electromagnet due to causing the current to flow in the exciting coils. The movable iron usually forms the armature of the electromagnet, held by a spring near the poles but not in contact with them. In purely electromagnetic systems the armature is attracted when the current flows in either direction. In many of these devices the electric circuit includes a contact breaker so arranged that the movement of the armature towards the electromagnet causes the circuit to be interrupted; the core then becomes demagnetized and the armature is drawn back by the spring. In this way vibratory movement of the armature can be maintained by the current which is rendered intermittent by the movement. This combination of electromagnet and contact breaker is used in electric bells, electromagnetic hammers and electric motor horns. In all such mechanisms the movement produced by the magnetic action is such as to diminish the reluctance of the magnetic circuit. The magnitude of the attraction per unit area of the surface of the armature, where the normal flux density is B, is represented approximately by $B^2/8\pi$.

There are several devices in which the range of movement of the iron is greatly increased. One of these is the "coil and plunger" arrangement, in which a movable bar of iron, having one end within a coil, is drawn further within the coil when the current flows in either direction. If, instead of a bar of iron, a bar of permanently magnetized steel is employed, the arrangement becomes a "polarized system," in which the movement is reversed by a reversal of the current. In telephone receivers and wireless loud speakers the current supplied is in the form of very feeble alternating current, and the attraction on the armature, being proportional to B^2, would be very small if the system were purely electromagnetic. If, however, the cores form polar extensions of a permanent magnet, by which they are magnetized to a suitable flux density B, the displacement of the armature due to a weak current in the coils, producing a proportional change δH in the magnetizing force, is proportional to $\delta B^2/\delta H$, *i.e.*, to $B.\delta B/\delta H$. The displacement is thus proportional to the product of the flux density B and its rate of variation with magnetizing force $\delta B/\delta H$. The value of $B.\delta B/\delta H$ depends upon the permeability and hysteresis of the cores, since we are here dealing with small cycles of flux superposed upon the constant flux due to the permanent magnet. Materials of high permeability, such as silicon steel, are found to have the greatest values of $B.\delta B/\delta H$, and in some telephone receivers the cores and the diaphragm (which here forms the armature) are made of this material. The factor $\delta B/\delta H$ also depends upon the reluctance of the air gaps and other parts of the magnetic circuit traversed by the alternating flux, and to produce the greatest sensitiveness the reluctance must be kept as small as possible. In this respect the presence of the steel magnet in the magnetic circuit is not very favourable.

FIG. 6.—DIAGRAM SHOWING ACTION OF MAGNETIC SEPARATOR PULLEY, USED FOR SEPARATING MAGNETIC FROM NON-MAGNETIC METALS

Another type of mechanism has come into use (especially in loud speakers) in which the received and amplified alternating current, instead of flowing through coils fixed on the cores of a magnet, flows through a movable coil placed in the annular gap of an electromagnet of suitable form. Details of this "moving coil" system will be found in the article TELEPHONE.

ELECTROMAGNETIC THEORY OF RADIATION. About 1855 Clerk Maxwell discovered equations which govern the behaviour of electromagnetic oscillations. He was able to show that these equations were equally applicable to light. It was in consequence of this discovery that he put forward the theory (the electromagnetic theory of light) that light was an electromagnetic phenomenon. (*See* ELECTRICITY and LIGHT).

ELECTROMETALLURGY. As different methods of producing electric currents in increasing magnitude were discovered, one of the earliest applications made, in every case, was the study of their effects on chemical change both by electrolytic action and, on account of the high temperatures attainable, by their electrothermal effects. Thus Davy in 1810, using a voltaic pile of 1,000 plates, isolated the alkali metals and aluminium by electrolysis, and conducted experiments on the fusion of iron wire. Pepys, in 1815, by means of an electrically heated iron rod demonstrated

the cementation of iron by absorption of carbon. The experiment was conducted by bending a piece of soft iron, cutting a longitudinal groove at the bend, and filling with diamond dust. The wire was then mounted between wider metal poles, and, after covering with talc to protect from oxidation, was heated by the passage of an electric current when the diamond was absorbed and the iron converted into steel.

Despretz in 1849 carried out experiments in which high temperatures produced electrically were utilized. The earlier work forms the subject of a paper entitled "The Fusion and Volatilization of some Refractory Bodies: Notes on some experiments carried out with the triple acid of the voltaic pile, the sun, and the blow-pipe" (*Comptes Rendus*, 1849, xxviii. 755). In later experiments an apparatus is described which consists of a tube of sugar-charcoal about ¼ in. wide and ½ in. long closed by two charcoal plugs which, with its contents, was raised to a high temperature by the passage of an electric current.

H. Wilde, in 1886, by means of a current from one of the earliest types of magneto-electric machines, was able to melt a bar of platinum 6 mm. thick and 2 ft. long. William von Siemens, in 1878, designed several forms of arc furnaces which contained all the important features of modern types. One, referred to in many textbooks, has a carbon electrode adjusted to the distance necessary to maintain an arc with the desired current by a magnetic solenoid operated by the main current passing through a surrounding coil. The crucible is insulated by surrounding it with carbon packed in a wider container. In place of a carbon electrode an adjustable water-cooled iron electrode, was also employed, as being more effective. One of the earliest electric furnace processes to be brought into commercial operation was that of the Cowles Brothers which was installed at Milton, Staffordshire, in 1886 (*Industries*, 1888, vol. v., 237). The process consisted of the reduction of alumina by carbon in the presence of iron or other metals, resulting in the formation of aluminium alloys. The furnaces were rectangular in shape, constructed of fireclay, and provided at either end with an inclined cast-iron pipe, through which the electrode was introduced. Heating was brought about by the formation of an arc between the carbon electrodes.

Each electrode consisted of a bundle of from seven to nine carbons (each 2½ in. diam.) held together by a cylindrical head of metal which was connected to the flexible cables leading in the current. The charge consisted of a mixture of corundum (Al_2O_3), metal and charcoal. A current of 5,000 amp. at 60 volts was passed and a period of one and a half hours was required for the reduction ot each charge. The furnace was covered with a cast-iron case provided with a hole in the centre, through which the gases generated during the process escaped. The reduced aluminium and alloying metal were volatilized, and the ascending vapours became condensed in the upper and cooler layers of charcoal. Combination occurred here and the liquid alloy flowed to the base of the furnace and was run off through a tap-hole. The daily output at Milton amounted to about 20 cwt. of ferro-aluminium or aluminium bronze containing 15 to 17% aluminium. The current was obtained from a Crompton dynamo of 300 kw. capacity, and its capacity constituted at that time a record in electric generators.

FIG. 1.—MOISSAN ELECTRIC ARC FURNACE

An arc is formed in a limestone block cavity, a little above the substance to be treated

In 1887 Héroult, in France, and Hall in America, devised an electrolytic process for the production of aluminium and the Cowles process suspended operation.

Moissan, commencing in 1892, carried out a series of experimental researches with the high temperatures obtained by means of an electric arc furnace. Metals such as chromium tungsten, molybdenum, uranium and titanium were thus obtained in a fused state for the first time. The method adopted, as illustrated in fig. 1, consisted in placing a powerful arc in a cavity of minimum size in a limestone block and at a certain distance above the substance to be heated. In this way, actual contact with the carbon vapour from the arc is avoided and at the same time the thermal action of the current is separated from any electrolytic effect. The current generally used by Moissan was about 450 amp. at 60 volts. This type of furnace, which is still suitable for many laboratory experiments, consists of two slabs of lime carefully cut and superposed. The lower slab has a long groove in which the electrodes rest, and in the middle is a small cavity which serves to hold a small carbon crucible containing the substance to be heated. The electrodes are easily rendered movable by means of two adjustable supports, or better, by using two sliders which rest on a bed-plate. The freedom of motion of the electrodes enables an adjustment of the length of the arc to be conveniently made. The arc at first is less than 1 cm. long, but towards the end of the experiment the length usually increases to from 2 to 2·5 cubic metres. If the furnace is filled with a good conducting metallic vapour (*e.g.*, aluminium), the electrodes may be 5 to 6 cm. apart. The length of the arc will thus be regulated so that an approximately constant resistance can be maintained.

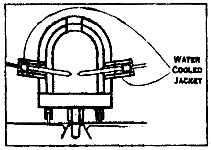

FIG. 2.—STASSANO ROTATING FURNACE

Heating is effected by downward radiation from an arc formed between three equidistant electrodes

Electric Smelting of Iron Ore and Production of Steel.—The principle of the Moissan furnace was applied by Stassano in Turin in 1903 for the smelting of iron ore and production of steel. A type of furnace arranged to rotate about an inclined axis which was finally adopted is illustrated in fig. 2, which shows a vertical section through two electrodes. Three equidistantly-spaced electrodes are employed in the larger units in order to utilize three-phase current. The electrodes are surrounded by water-cooled jackets. Gases from the reaction pass out through a vent at the head of the enclosure and the furnace is provided with a charging hopper and tapping spout not shown in the diagram. The furnace was originally employed for the smelting of magnetite and haematite whereby malleable iron was produced directly, and later for the production of steel from cast-iron and turnings.

Large-scale experiments on the electric smelting of iron ore and the production of ferro alloys were undertaken at Sault Ste. Marie, Canada, by a commission appointed by the Canadian Government in 1903. The furnace consisted, as seen in fig. 3, of an iron casing, bolted to a base plate of cast-iron. Rods of iron were then cast into the plate to secure a good contact with the carbon paste rammed into the lower part of the furnace and lining the bottom and sides of the crucible. One end of the electrode was planed to fit into a steel shoe and was held tight by means of wedges. A pipe was put in the electrode holder, through which a current of air was circulated on to the holder. The power applied was 200 kw. single phase alternating current at a mean value of 5,000 amp. at 40 volts. By the use of charcoal as reducing agent it was shown that magnetic ores could be smelted efficiently in this form of electric furnace, though the ore is too high in sulphur to be treated by the usual blast-furnace process. It was also shown that a ferro-nickel pig could be produced practically free from sulphur and of fine quality from roasted nickeliferous pyrrhotite.

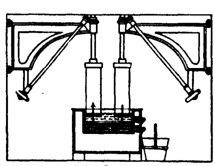
FIG. 3.—FURNACE FOR ELECTRIC SMELTING OF IRON ORE AND THE PRODUCTION OF FERRO ALLOYS

For the production of steel the main advantages which have been gained by the employment of electric furnace operation is

that a product can be obtained which is equal to the best grade of crucible steel at a considerably lower cost and on a much larger scale than is possible with the crucible process. The advantage is mainly due to the higher temperature of operation which is possible in the electric furnace and this gives more latitude in the composition of the slags which are employed for the removal of sulphur and phosphorus. Access of nitrogen to the metal which has a deleterious action, can moreover be more completely excluded by the electric furnace, and manganese and other metals employed in the purification can be added with less loss through oxidation.



FROM PRING, "THE ELECTRIC FURNACE"
FIG. 4.—HÉROULT DIRECT-ARC FURNACE
Arcs are formed between the surfaces of the charge and carbon electrodes suspended vertically over the furnace

The three main types of electric steel furnaces now in use are (1) the direct arc type, (2) the radiation arc type and (3) the induction furnace.

Direct Arc Furnace.—The main example of this type is the Héroult furnace, the principle of which is illustrated in the diagram in fig. 4.

This furnace is operated by forming arcs between the surface of the charge and carbon electrodes which are suspended vertically above the furnace and connected to the poles of an alternating current supply.

Formerly only single-phase current was used together with two electrodes joined in series, but the larger furnaces now in use are operated with three-phase current and contain three electrodes. In all cases when the furnace charge is molten, the current, as shown in fig. 4 passes in the form of an arc from the electrode to the surface of the slag, through the slag to the metal, and horizontally through the surface layers of the metal to the adjacent electrode where a second arc is formed. A zone of very high temperature is thus produced in the slag in the neighbourhood of the electrodes, and rapidly brings about the chemical reactions involved in the purification of the iron and its conversion into steel.

These furnaces are all fitted with a tilting mechanism and a spout so as to enable the fused slag or metal to be poured.

A variation in the design of the Héroult furnace is shown in the Snyder furnace, which as originally designed for single-phase current is illustrated in fig. 5.

The main features of the furnace are a hinged roof which enables the roof, electrodes and all overhead gear to be removed by a pivoted mechanism. This device facilitates charging and enables mechanical charging to be employed. With the single-phase type, the current enters by the cables shown at the base which lead to the central carbon electrode at the top and after forming an arc between the electrode and the surface of the bath, the current leaves the furnace through a water-cooled metal contact at the base. A number of advantages are obtained by the use of single-phase units chiefly due to the central distribution of the current. Single-phase units are, however, limited to sizes of a capacity of about one ton. For larger furnaces a system has consequently been adopted which makes use of three-phase current, two phases being connected to two top or movable carbon electrodes, while the third is connected to the metal electrode through the hearth.

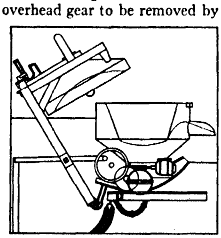


FIG. 5.—SYNDER FURNACE
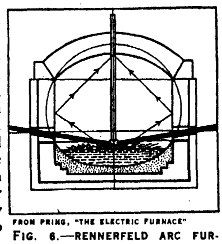
In this furnace a hinged roof enables the roof, electrodes and all overhead gear to be removed by a pivoted mechanism

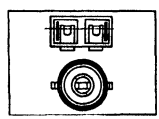
Radiation Arc Furnace.—The chief example of this type of furnace is that of Stassano, which is described above. A modification of this is in the Rennerfeld arc furnace. In this system the electrodes are arranged so that the arc is deflected downwards away from the roof and on to the charge in the furnace. As shown in fig. 6 the two side electrodes are arranged slightly inclined to the horizontal, while the third electrode is suspended vertically in the centre of the furnace in a position equidistant from the ends of the side electrodes. By means of the so-called Scott-connections the electrodes are joined to a three-phase current supply in such a way that the middle or vertical electrode forms the common return for the two phases, and thus carries about 40% more current than the side electrodes. The electro-magnetic action of the current arranged in this way causes the flame of the arc to strike downwards and spread over the surface of the thinned slag. The furnace is supported on trunnions and arranged to tilt. The usual size of a Rennerfeld furnace is three tons, though 12 ton and larger units have been designed. The current supply for a three-ton furnace is usually 3,750 amp.$\times$100 volts$\times$2$=$750 k.v.a.



FROM PRING, "THE ELECTRIC FURNACE"
FIG. 6.—RENNERFELD ARC FURNACE
Electrodes are so arranged that arc is deflected downwards away from roof and on to charge in furnace

Induction Furnaces.—In the usual type of induction furnace the crucible holding the metal under treatment is in the form of a ring or loop and constitutes the single-turn secondary of a transformer. The iron core or yoke of the transformer passes through and interlinks the primary coil with the single-turn secondary and thus provides the necessary close coupling between the two. The first example of an induction furnace was designed by Ferranti (Eng. Pat. 700 of 1887), while the first practical type to be brought into industrial use was constructed by Colby in America in 1890. This contained a double-yoked magnetic core and a primary winding which in an early type was arranged outside the metal bath as shown in fig. 7, but in a later development the primary winding was placed in the centre of the metal ring, as in the Kjellin furnace. A unit of 130 k.v.a. capacity holding about 190 lb. of steel was installed in Philadelphia about 1906 for the manufacture of high-grade steels. The primary consisted of 28 turns of copper tube cooled by water circulation and arranged to utilize 540 amp. at 240 volts.

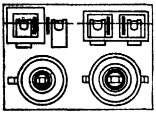
The main advantages obtained by induction furnaces are the absence of contamination of the metal by contact with carbon electrodes; better exclusion of furnace gases from the metal; convenience in introduction of current in that a high potential circuit can be supplied without the use of transformers or copper cables of large cross-section; fluctuations of the current do not occur as in other types, and a much steadier load is therefore offered to the power supply. Tappings are obtained which are very large compared with the contents of a crucible, and the steel produced is stated to be of better quality than that given in crucibles from the same raw material. The alternating current, through its electro-magnetic action, causes an efficient circulation of the metal. One disadvantage, however, in the original type of furnace, containing a ring of metal of uniform section, is that the temperature could not be taken to the same high degree as in the direct arc type, and the powerful reducing action which is accompanied by the formation of calcium carbide is thus not secured. On account of this lower temperature the furnace could not be applied for carrying out any extensive refining, but rather a melting which required the use of pure materials in order to yield a high grade of steel. However, in more recent types of the induction furnace attempts are made to overcome this limitation by arranging a narrowing of the channel of a portion of the circuit, or by other means causing an increased resistance and higher temperature to be obtained locally. A good



FROM PRING, "THE ELECTRIC FURNACE"
FIG. 7.—COLBY INDUCTION FURNACE
This contains a double-yoked magnetic core and a primary winding arranged outside a metal bath

circulation of the metal is in all cases ensured in the induction type of furnace through the operation of electro-magnetic forces.

The Kjellin furnace was introduced in 1899, and as seen in figs. 8 and 9 contained either a single or double yoke core with one primary winding in the centre. The Kjellin furnace was erected at Gysinge in Sweden and applied to the production of steel in 1900. Larger units of this furnace were later installed at the Röchling steel works at Völklingen, Essen, Germany. Furnaces of 750 kw. capacity were operated with single-phase current of five periods at 4,500 to 4,900 volts. The circular crucible of this furnace, which had a capacity of 85 tons, was built up from masonry and lined with a suitable basic material as used in the Bessemer converters or Siemens-Martin furnace. During operation the annular crucible is roofed over by covering with segmental iron plates. The furnace is arranged to tilt and is provided with a pouring spout for emptying. The Kjellin furnace has proved to be very suitable for making the highest class of steel from pure raw materials, and has been able to compete with the crucible process for this purpose, even when the power is generated from coal.



FROM PRING, "THE ELECTRIC FURNACE"

FIGS. 8 & 9.—KJELLIN FURNACES, CONTAINING EITHER SINGLE OR DOUBLE YOKED CORES

The main disadvantages of the Kjellin furnace are the inconvenient shape and narrow width of the annular crucible which prevents the hearth from being readily accessible and easily surveyed, and the specially low frequency of the alternating current required in the larger furnaces, which involves the construction of special expensive generators. The above disadvantages have for the most part been overcome in the modified type of induction furnace devised by Röchling and Rodenhauser, and this has now generally replaced the earlier type of Kjellin furnace.

Röchling-Rodenhauser Furnace.—The Röchling-Rodenhauser furnace was first brought into operation in Germany in 1906 for the final refining of fluid steel which had first been treated in the Bessemer converter. The chief features which distinguishes it from the Colby-Kjellin type is that the crucible, instead of being in the form of a plain ring, is arranged in the shape of a figure 8, with a wide central space. Heating is effected by a combination of two systems. Firstly, by induction currents, whereby the furnace acts like two combined ordinary induction furnaces, and secondly, by an auxiliary circuit in which by means of a separate winding around the primary coil an induced current is applied to the metal bath through electrodes consisting of plates of soft cast-steel covered by grids of refractory oxides which become conducting by electrolytic action at high temperature. A diagram of the furnace as designed for single-phase current is shown in fig. 10 in horizontal plan. Like the ordinary induction furnace, this furnace is essentially a transformer with a single primary winding A around both cores H of the transformer. The secondaries are two in number, one is the molten bath C in the form of a figure 8, the channel D between the two cores being comparatively broad and the other consists of extra windings B surrounding the primary coils and conducting currents to the metallic plates E which are inserted in the furnace walls, and are raised to a high temperature by the passage of the current to the metal bath. During operation the molten charge is kept in good circulation by the electromagnetic influence of the current. The whole furnace is built as a tilting furnace by mounting on rollers, and in general design is similar to the Siemens-Martin open-hearth furnace.

The disadvantage attending the generation of single-phase current has been overcome by a three-phase induction furnace, which in units of from 3 to 15 tons capacity is operated with a frequency of 50 periods, and thus makes possible the use of standard three-phase generators.

The hearth shown in the 1·5-ton furnaces is 1 ft. 7 in. wide, and 4 ft. 9 in. long. The three transformer cores are surrounded by heating channels. At the places in which two such channels enter into the main hearth, special electrode plates are arranged with great care in the general form of rectangular black slots built in the furnace walls. These electrodes are embedded in the furnace wall and separated from the fused charge by a refractory wall which becomes conducting when heated. Each of the three transformer cores is provided with a primary winding, and above each primary winding a secondary winding is also arranged. While one end of the latter is connected to a bus-bar, the other ends of the three windings are connected to the three electrodes.

At the Röchling steel works in Germany, the procedure most generally adopted is a "triplex" treatment, in which the steel is first "blown" in a convertor, further purified in a basic open hearth, and then subjected to a final refining treatment in the electric furnace. At present the largest application of electric steel furnaces is in combination with the older fuel-heated furnaces to give the final refining to molten steel which has undergone a preliminary treatment in the convertor or open-hearth furnace.

FIG. 10.—RÖCHLING-RODENHAUSER FURNACE

Crucible is arranged in form of a figure 8, with a wide central space

Electrolytic Processes with Fused Electrolytes.—The procedure in all instances in the production of metals from fused components consists in utilizing the property these compounds possess of becoming conductors at high temperatures. Electrolytic dissociation is thus brought about as in aqueous solutions at ordinary temperatures. By the application of a suitable potential, the cation is then separated in the metallic condition on the surface of the cathode. During the electrolysis, the necessary high temperature may be maintained through heat generated by the passage of the current.

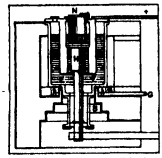
Aluminium.—In all methods which have so far received practical application, the preparation of aluminium is brought about by dissolving alumina in the halogen compounds of the alkalis, alkaline earths or of aluminium, and separating the aluminium by electrolysis.

The raw materials employed consist almost exclusively of bauxite, which is a hydrate of alumina of the formula $Al_2O_3{\cdot}3H_2O$ and cryolite which has the composition $3NaF{\cdot}AlF_3$. An addition is generally made to the bath of an excess of aluminium fluoride, calcium fluoride, sodium chloride or other compounds in order to reduce the melting point of the electrolyte and diminish its density so as to facilitate the sinking of the aluminium to the bottom of the bath.

It is necessary to submit the alumina employed to a careful purification and to prepare it in a physical condition which enables solution to take place rapidly in the molten bath. During the electrolysis, aluminium is liberated at the cathode and oxygen at the anode which reacts with the carbon to form carbon monoxide. At the same time small amounts of fluorine are sometimes liberated, the decomposition voltage of the fluoride being only slightly above that of alumina. It is necessary to adjust any loss of fluorine from the bath by the addition of aluminium fluoride. Alumina is replaced as the electrolysis proceeds and the composition of the bath remains constant. This method, based on the power of electricity to split metal salts into their components had been discovered many years before it was possible to apply it commercially. Early attempts to electrolize aqueous solutions had failed because the aluminium produced at once recombined with water. Robert Bunsen, 1854, passed a current through a molten mixture of aluminium chloride and common salt, splitting the former into chlorine, which escaped, and aluminium which he collected as metallic beads.

Héroult Process.—In this process electrolysis was at first attempted by the use of alumina alone as the charge. In this case the high temperature necessary for the reaction resulted, when using a carbon cathode, in the formation of aluminium carbide. Cathodes of copper and other metals were accordingly applied and aluminium alloys prepared. Later, by the use of cryolite as a flux or solvent, the separation of aluminium metal was found possible when using a cathode either of iron or carbon. The anode, in this apparatus, consisted of a bundle of carbon poles fastened together by copper bands so as to form a block 1 m. long and 0·25

sq.m. section. The type of furnace adopted later and installed at Neuhausen is shown in fig. 11. The anode consists of a bundle of rectangular plates of carbon which are cemented together by means of a mixture of carbon with tar and molasses or glucose solution. The cathode consists of a carbon block contained in an enclosing metal case. The roof of the furnace is covered with graphite plates k, furnished with openings for the admission of the anode in the centre and the charge at C. The temperature of the bath is from 800° to 1,000° and the most favourable composition a mixture of cryolite with 10% alumina. The aluminium collects on the bed of the cell from whence it can be removed by tapping. The specific gravity of the molten metal is 2·54 while that of the fused bath is 2·35.



FROM PRING, "THE ELECTRIC FURNACE"

FIG. 12.—CASTNER SODIUM CELL

An iron cylinder, suspended in fused electrolyte above the cathode, collects the liberated sodium

Sodium.—The industrial preparation of sodium was developed by Castner, through investigations begun in 1888, on the electrolysis of fused sodium hydroxide. The apparatus designed by Castner consists, as shown in fig. 12, of a cast-iron case A of about 14 in. diam., the upper part being 24 in. high and provided at the base with an extension tube B of 3½ in. diam. and 32 in. long. The cathode H consists of a copper bar secured at the base of the surrounding case by a wooden plug, in the space above which fused sodium hydrate is filled and allowed to solidify. The electrolyte in the space above can be heated by means of the gas-ring burner G.

Directly above the cathode is suspended an iron cylinder, closed by the lid N which is provided with an opening for the escape of hydrogen, while from the lower part, a wire gauze cylinder extends so as to form a diaphragm between the electrodes and prevent the sodium after separation from diffusing to the anode. The anode E was originally made of an alloy of nickel and silver which was found resistant against corrosion.

The sodium liberated at the cathode H together with the hydrogen rises into the cylinder N, and is periodically removed by means of a perforated ladle which allows its separation from the fused electrolyte to take place.

Calcium.—In a process in operation at the Bitterfeld electrochemical works in Germany calcium is prepared from the fused chloride by means of an electrical process in which a cathode, which is kept cold, is, at its base so arranged as to make contact with the surface of an electrolyte of fused calcium chloride. On passing the current, calcium is separated in globular form, adheres to the cathode and solidifies. The electrode and adhering calcium are slowly raised from the bath so that a cylindrical rod of calcium is then gradually built up, and by means of the thin coating of chloride which adheres, is protected against oxidation.

ELECTRON, THE. One of the most important generalizations of all time is that of the electrical constitution of matter, for this conception underlies practically the whole of 20th century physics. It is customary to consider that it was introduced during the last half of the last decade of the 19th century; yet, to choose any particular year, or even decade, for the introduction of this idea is to sacrifice accuracy, for, in general, advances in science do not take place at any given time. It is as difficult to determine when a particular conception arises as it is to fix the instant at which the babe acquires consciousness. The progress of science takes place, for the most part, by a process of infinitesimal accretion. It is a process of growth, each experimenter adding a little to the structure reared by his predecessors. There is nothing in the history of science that illustrates this process more beautifully than does the history of the development of the idea of the electrical constitution of matter.

GROWTH OF THE ELECTRICAL THEORY OF MATTER

Franklin.—In the year 1756 Franklin, upon contemplating the phenomenon of electrostatic induction, said with amazing insight, "The electric matter consists of particles extremely subtle since it can permeate common matter, even the densest, with such freedom and ease as not to receive any appreciable resistance." And yet, for fully a hundred years, electric *particles* were hardly again mentioned.

Faraday.—In 1833 Faraday led one and the same electrical current simultaneously through a solution of a silver salt and through an acid solution (*i.e.*, a solution in which the positive ion was hydrogen) and found that the number of atoms of silver that came out of the one solution was exactly the same as the number of atoms of hydrogen that came out of the other, thus showing conclusively that one and the same quantity of electricity was associated in the electrolytic process with the atom of hydrogen and the atom of silver—a relation that holds for all univalent atoms. And yet Faraday himself, by his discovery of the effect of the medium about a conductor in changing the electrical forces emanating from it, was responsible for starting the period in which electrical phenomena were thought of almost exclusively in terms of stresses and strains in the medium surrounding the electrified body—a period in which Maxwell himself, one of the most outstanding intellects of the 19th century, and the follower and interpreter of Faraday and his work, said, "It is extremely improbable that when we come to understand the true nature of electrolysis we shall retain in any form the theory of molecular charges, for then we shall have secured a sure basis upon which to form a true theory of electrical currents and so become independent of these provisional hypotheses." So that Faraday's experiments certainly did not convince the world of the general correctness of the atomic theory of electricity.

Weber.—Wilhelm Weber (*Werke* iv., 1871) built up his whole theory of electromagnetism on what was essentially an electron foundation. The hypothetical amperean currents, long before assumed to be circulating around molecules and thus producing the effects of magnetism, he explained as due to the rotation of light, positively charged, particles about a heavy negative nucleus. And yet this idea was not taken up again until the time of Lorentz, and it surely did not get into the consciousness of mankind at the time of Weber.

Crookes.—In 1879 Sir William Crookes, in view of his experiments on cathode rays—in which he had both proved their ability to set wheels in rotation and to be deflected by a magnet, reached the definite conclusion that these rays consisted of a flying swarm of charged particles. Indeed, he said, "In studying this state of matter we seem to have at last in our grasp and obedient to our control little indivisible particles which with good warrant are supposed to constitute the physical basis of the universe." (Fournier d'Albe, *Life of Sir William Crookes*, 1924.) And yet his experiments were not convincing to the great body of German physicists who, as late as 1896, were asserting, in view of the great penetrating power which Lenard had shown the cathode rays to possess, that they were clearly of ethereal origin and not corpuscles at all.

Stoney.—In the year 1891, when Dr. G. Johnston Stoney (*Scientific Transactions of the Royal Dublin Society*, iv., 1891, 11th series) introduced the word *electron* to designate the elementary electrical charge, and actually computed the value of the electron by a method which is quite comparable in accuracy with any that was used up to 1909. The following quotations bear remarkable testimony to his insight:—"Attention must be given to Faraday's Law of Electrolysis, which is equivalent to the statement that in electrolysis a definite quantity of electricity, the same in all cases, passes for each chemical bond that is ruptured." The author called attention to this form of the law in a communication made to the British Association in 1874 and printed in the *Scientific Proceedings of the Royal Dublin Society*, of February 1881 and in the *Philosophical Magazine* for May 1881. It is there shown

that the amount of this very remarkable quantity of electricity is about the twentiethet (that is $\frac{1}{10^{20}}$) of the usual electromagnetic unit of electricity, *i.e.*, the unit of the Ohm series. This is the same as 3 eleventhets ($\frac{3}{10^{11}}$) of the smaller C.G.S. electrostatic unit of quantity. A charge of this amount is associated in the chemical atom with each bond. There may accordingly be several such charges in one chemical atom, and there appear to be at least two in each atom. These charges, which it will be convenient to call "electrons," cannot be removed from the atom, but they become disguised when atoms chemically unite. If an electron be lodged at the point *P* of the molecule which undergoes the motion described in the last chapter, the revolution of this charge will cause an electromagnetic undulation in the surrounding aether.

Also the following remarkable sentences are found in the same paper:—"Finally nature presents us with a single definite quantity of electricity which is independent of the particular bodies acted on. . . . This definite quantity of electricity I shall call E_1. If we make this our unit of electricity, we shall probably have made a very important step in our study of molecular phenomena. Hence we have very good reason to suppose that in V_1, G_1 and E_1, we have three of a series of systematic units that in an eminent sense are the units of nature, and stand in an intimate relation with the work which goes on in her mighty laboratory."

It will be noticed from this quotation that the word "electron" was introduced to denote simply a definite elementary quantity of electricity without any reference to the mass or inertia which may be associated with it, and Prof. Stoney implies that every atom must contain at least two electrons, one positive and one negative, because otherwise it would be impossible that the atom as a whole be electrically neutral. As a matter of fact, the evidence is now altogether convincing that the hydrogen atom does indeed contain just one positive and one negative electron. And yet, despite the clearness of Stoney's vision, the theory of the electrical constitution of matter certainly did not come into general acceptance in his time.

J. J. Thomson.—In 1897 J. J. Thomson proved the electrostatic as well as the magnetic deflectability of cathode rays, and showed by this work that the mass of the particles constituting these rays was of the order of a thousandth of the mass of the hydrogen atom. Indeed, it was at this time, and largely as a result of J. J. Thomson's experiments in England and Lenard's similar experiments in Germany in 1898, combined with the nearly simultaneous discovery of the Zeeman effect by Zeeman and Lorentz in Holland (1897), that the theory of the electrical constitution of matter began to be fairly generally accepted, and it is because of this fact that it is customary and proper to fix the birth of the electron theory at about this time; and yet, as late as 1905 or 1906, as eminent an authority as Roentgen would have nothing to do with the electron theory because he regarded it as an unproven and highly speculative hypothesis. What was actually proved in these experiments of Thomson's and Lenard's was that cathode rays are corpuscular in nature, and that if the charge on these corpuscles *be assumed* to be invariable, and equal to that carried by a hydrogen ion in electrolysis—a natural and, as later experiments proved, a correct assumption—then the mass of each one of them is of the order of one-thousandth of the mass of the hydrogen atom. These experiments also proved that these same cathode rays come out of all kinds of substances, when these different substances are made cathodes, in the passage of a discharge through highly exhausted tubes.

Later experiments by Wien (1898), Thomson (1913) and Aston (1922 and 1926), of precisely this same sort, on the masses or inertias of positive rays instead of cathode rays have shown that the positive electron, while it is a charge of equal amount but opposite sign to the negative, is always associated with a *mass* about 1,845 times greater. The positive electron is sometimes called the proton, and the word electron, when used without any qualifying adjective, is usually understood to refer to the negative electron, but it is important to remember that historically, derivatively and logically the word *electron* means, as indicated above, the unit *charge,* and carries no implication as to mass.

Early Work on the Electron.—Even earlier than the work referred to in the preceding paragraph, a beginning toward the determination of the value of the electron, the unit charge, or the atom of electricity, had been made by G. Johnston Stoney in 1881. The next attempt was made by Townsend in 1897, a third by Sir J. J. Thomson in 1898, a fourth by H. A. Wilson in 1903 and a fifth by Millikan and Begeman in 1908. But all of these workers used methods which involved such uncertain assumptions that no precision of measurement was or could be claimed. Nor were the results themselves thus far of appreciably greater certainty than could be obtained from the Faraday constant ($Ne = 9649{\cdot}4$) and kinetic theory estimates of the number of molecules N in a given molecule, which yielded a value of about 3×10^{-10} electrostatic units. Indeed, up to this point there was no method available that could yield anything more than the *mean* charge on a great number of particles, generally the particles of electrified clouds, and it is now known that the particles of such clouds carry in general widely varying charges, so that there was no certainty at all that this mean charge was the electron itself, and no *direct* proof that electrons were all exactly alike in charge. This proof was furnished, however, by the development of a technique that was first used in 1909, a technique with the aid of which the electron itself was first isolated and accurately measured, its value being soon fixed at $4{\cdot}774 \times 10^{-10}$ absolute electrostatic units of electricity. This means that the electron is so small a quantity of electricity that it takes $\frac{1}{4{\cdot}774 \times 10^{-10}}$, or about two thousand million of them to make up the very minute unit of electricity defined in the next paragraph.

ISOLATION OF THE ELECTRON

Definition of Positive and Negative Electric Charges.—It will probably be agreed that the most unambiguous single bit of evidence for the atomicity of electricity is found in the "oil-drop experiment," which puts the proof both of the unitary nature of electricity and of the electrical constitution of matter into such simple and unquestionable form that one needs, as a background, little more than a bare definition of electricity in order to see that both results follow from the experimental facts.

What, then, is electricity? Of its ultimate nature we know very little, precisely as we know very little of the ultimate nature of matter, or of the ether, or of mind, or, indeed, of the ultimate nature of anything. Science does not deal with ultimates, but rather with relations between observed or observable phenomena. Our ignorance of ultimates, however, does not prevent us from setting up a sharp, quantitative definition of an electric charge which anyone can understand. Everyone knows that, if he combs his hair with an ebonite comb, both the comb and his hairs acquire strange new properties of such sort that the hairs violently repel one another and are equally violently attracted by the comb. The forces thus called into play are enormously stronger than the gravitational forces acting upon the hairs. Merely for the sake of having a name by which we can describe and remember them we call them *electrical forces,* and the bodies that exhibit them are *by definition* said to possess *charges of electricity.* Again, since a glass rod that has been rubbed with silk violently repels hairs or other light electrified bodies that are violently attracted by ebonite that has been passed through hair or been "rubbed with cat's fur," we arbitrarily say that any electrified body that is repelled by a glass-rod-rubbed-with-silk possesses a charge of *positive* electricity, and any body that is repelled by an ebonite-rod-rubbed-with-cat's-fur possesses a charge of *negative* electricity. These are then altogether unambiguous and easily intelligible definitions of positive and negative electricity.

Further, we quite naturally measure *the amount of electricity* on a given body by the amount of the force exerted upon it at a given distance by some glass rod or other body which has been rubbed or treated in some standard way. Quite specifically, we define unit electric charge as that charge which, placed upon a minute spherical pithball, will repel with a force of one dyne

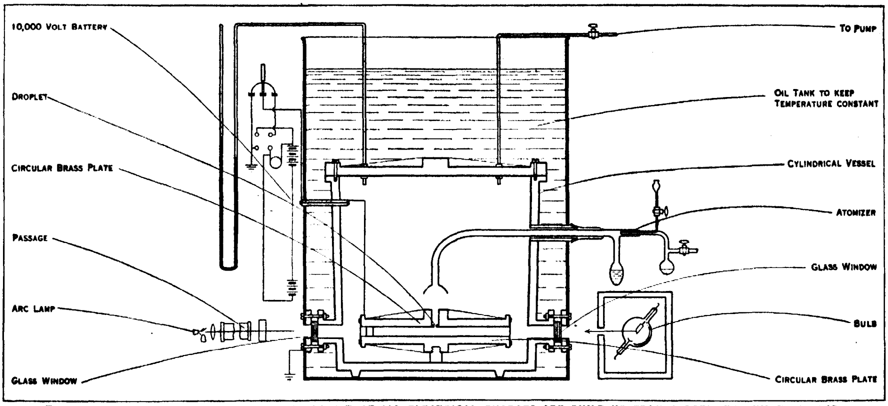

FIG. 1.—DIAGRAM OF APPARATUS MADE TO PROVE THAT ALL ELECTRICAL CHARGES ARE BUILT UP FROM A DEFINITE NUMBER OF DISCRETE UNITS (ELECTRONS), ALL EXACTLY ALIKE
Droplets of oil are placed in a strong electrical field, the changes of force experienced by them being measured

(about a milligram weight) another similar pith ball, charged in exactly the same way and placed one centimetre away from it. This is the definition of the so-called *absolute electrostatic unit of electricity* spoken of in the preceding section.

Criterion for Atomicity.—If, now, we wish to put to nature the exceedingly important and very fundamental question, is electricity something that exists in discrete elements or particles, as Franklin imagined it to be, and, if so, are these particles all alike—*i.e.*, is electricity atomic in structure?—it is quite obvious from the foregoing definitions that the simplest and most direct way possible of proceeding in the attempt to get the answer is to take the very smallest obtainable body which can be made to acquire an electrical charge, to measure the electrical force exerted upon it at a given distance by some standard body of invariable charge, then to change the charge on this very small body by the smallest possible amounts, and finally to see whether the forces exerted upon it by the standard body in the course of these changes show any *unitary* properties, *i.e.*, whether they increase by unit steps or do not so increase. If they do so increase, then the charges here dealt with will have been definitely shown to be multiples of a unit charge. If they do not so increase, we shall not yet be able to deny the atomic or unitary structure of electricity, but we shall be certain that, if it has a structure at all, it must be a much finer grained structure than corresponds with the minute changes of charge which we have in these experiments been able to use.

Oil-drop Experiment.—Experiments of this kind were first undertaken in the year 1909. The very minute bodies, the changes in charge of which were to be observed, were the minute droplets of oil in an oil-spray such as is formed by an ordinary toilet atomizer. These were chosen, first, because it was necessary to obtain minute bodies which would not evaporate (modern clock and watch oils represent a hundred years of effort in the development of non-evaporable and non-gumming, lubricants) and, secondly, because these droplets of oil-spray were as minute spherical bodies as anyone could ever hope to obtain and still have them visible; so that the changes in the force exerted upon them by a constant electrical field could be accurately measured. The constant electrical field was obtained by attaching the terminals of a ten-thousand volt battery to the circular brass plates (fig. 1) held about 16mm. apart by three insulating posts. This arrangement produced an altogether uniform and constant electrical field between the plates, and a charged oil drop in that field would have imparted to it, by the field, a speed which, according to the well-known laws of motion of a small body through a resisting medium, would be strictly proportional to the charge upon the drop. The actual procedure was first to disconnect the battery from the brass plates, short-circuiting them in so doing so that no field existed between them, then to send a puff of air through the atomizer, thus producing a cloud of oil droplets above the minute pin-hole in the middle of plate. One or more of these droplets would then find its way through this pin-hole into the space between the plates. This droplet was rendered visible by passing a powerful beam of light from an arc between the plates and looking through a short-focus telescope at the droplet in a direction nearly at right angles to the beam. In this beam the droplet appeared like a bright star floating slowly downward toward the lower brass plate. Before it struck the plate the switch was thrown so as to create the electric field in the space between the plates. The droplet, if properly charged by the frictional process involved in blowing the spray, would then begin to rise against gravity, because of the pull of the field on its charge. Just before it could strike the upper plate, the field would be thrown off by opening the switch, and the droplet would then begin to fall again at exactly its former rate. Its successive times of fall under gravity and of subsequent rise under the action of the field were then taken. The table gives a typical set of readings, the first column headed g giving the successive numbers of seconds required for the droplet to fall, with no field on, the distance between two fiducial marks in the eyepiece which corresponded to an actual distance of fall of exactly ·5222cm. The second column headed f, gives successive numbers of seconds required for the droplet to rise under the action of the field upon its charge. Between the second and third trips up, the charge on the droplet was changed by passing *underneath* it a beam of X-rays from the X-ray bulb I, and it is sufficient, for the present, to know that this procedure does change the charge, leaving to a later time the discussion of why it changes it. Similarly, a change in charge was brought about between the third and fourth trips up, the fourth and fifth, the sixth and seventh, the ninth and tenth, and the eleventh and twelfth.

Proof of Atomicity.—Now, the striking result which appears at once from a glance at column f is that only a few definite *times of rise* seem to be possible, and these recur continually, thus indicating that *only certain definite charges can be placed upon the drop.* These charges are proportional to the speeds imparted by the field, and, since the action of the field is first to neutralize the downward speed, imparted by gravity, and then to impart an upward speed in addition, the total speed imparted by the field is actually obtained by adding v_1, the downward speed due

to gravity, and v_2, the upward speed in the field. The results of such addition are shown in the middle portion of the table under the heading (v_1+v_2). The difference between the first two of these, corresponding to the two times of rise 34·7sec. and 85·0sec., respectively, is ·05347—·04456=·00891, which therefore represents, in terms of a speed, the charge *caught from the air* between the fourth and fifth trips up. When the whole succession of

observed speeds imparted by the field is divided through by the integers 5, 6, 7, 8, 9, respectively (*see* lower part of table), there results in each case a number which is ·00891 within the very small limits of observational error. This shows conclusively, first, that the charge captured from the air when the time of rise changed from 34·8sec. to 84·5sec. was itself the *elementary unit of charge*, and, second, that the droplet carried successively 5, 6, 7, 8 and 9 of these units. In other words, the charges which the droplet is able to carry do show very definitely, unitary relationships, and the number of units (*electrons*) on the drop at any time can be counted by the foregoing process with quite the same certainty with which we can count our fingers or toes.

Since the foregoing sort of tests have been extended to thousands of droplets made of many different substances, some of which are insulators like oil, some semi-conductors like glycerine, some excellent conductors like mercury, and always with results precisely like those just presented, there is clearly no escape from the conclusion that *all electrical charges are built up out of a definite number of discrete elements or particles all exactly alike.* Indeed, anyone who has seen the foregoing experiment, and hundreds, perhaps thousands, have now done so, has proved for himself the existence of the electron with just as much certainty as if he had seen it as a visible object.

Electrons as Constituents of Atoms.—The experiment shows also that, since the X-rays were passed beneath the drop and were not incident upon it, the changes in charge must necessarily have been due to charges *knocked out of the atoms* of nitrogen and oxygen, by the passage of the rays, and caught by the drop, or thrown into it by the electric field. Since these charges were found to be electrons the experiment furnishes definite proof that ordinary *atoms have electrons as constituents.*

The electrons thus knocked out of atoms by X-rays or by ultraviolet light are found by slight variations of this same experiment to be always negative in sign. One such variation was as follows:—When the suspended droplet was of mercury and the exciting narrow beam was of ultra-violet light instead of X-rays the droplet did not change its charge when the beam passed underneath it (ultra-violet light has not a sufficiently short wave-length to detach electrons from the molecules of nitrogen or oxygen) but only when the light shone directly on the droplet itself; and then the sudden changes in its motions were always such as to show that it was invariably a negative, never a positive, electron that was detached from the mercury atoms of the drop by the incidence of ultra-violet light. These and slightly different experiments with X-rays show that it is only the negative, never the positive, electronic constituents of atoms that can be detached by external agencies such as molecular bombardment, incident aether waves, or temperature. As a matter of fact we now know that all the positive electrons in an atom are concentrated in its very minute nucleus.

Further in the course of the oil-drop experiment it was found possible to change the charge on the droplet, and to obtain an oil or a mercury drop altogether electrically neutral, which therefore falls under gravity with exactly the same speed when the electrical field is on as when it is off—a very important fact from which it follows that the negative constituents of the mercury, or other atoms, have as partners in the drop exactly as many unit positive charges as they have negative charges. In other words, we have here evidence that all atoms of which we have any knowledge have in them a certain definite number of negative electrons and exactly the *same number of positive electrons,* else they could not be obtained in the neutral condition. (This number can now be counted with certainty by a number of methods, the simplest being the method of Moseley.)

The discovery of the unitary or electronic structure of electricity means, of course, that all electrical phenomena must henceforth be interpreted in terms of the positions and movements of positive and negative electrons.

Absolute Value of the Electron.—The measurement of the absolute value of the electron was made by means of the oil-drop method, and involved a very large number of precise measurements of the foregoing sort upon a very large number of oil-droplets of widely varying sizes, floating, or falling, in many different sorts of gases, at many different pressures varying from one and a half millimetres of mercury up to 760 millimetres. By such a series of measurements the results were made independent of the gas pressures, and of the individual properties both of the droplets and of the media in which they floated. The details of these measurements will be here omitted, and only the final result stated; viz., that all the different series of measurements on different drop-substances and in different media always pointed infallibly, as shown by the convergence point of fig. 2, to the value $e^{2/3}=61\cdot 085\times 10^{-8}$, which corresponds to the absolute value of the electron $e=4\cdot 774\times 10^{-10}$ absolute electrostatic units, or $1{,}592\times 10^{-20}$ electromagnetic units. This is correct to about one part in a thousand.

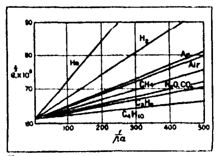

FIG. 2.—ABSOLUTE VALUE OF THE ELECTRON

From various experiments this has been established as a constant, $e = 4.774 \times 10^{-10}$ absolute electrostatic units

The electron is one of the most important of all physical constants; for the absolute magnitudes of practically all molecular and atomic quantities are determined as soon as it is accurately known, but they are indeterminable without it. Thus, for example, the so-called Faraday constant, the amount of electricity required to deposit from a solution one gramme molecule of a univalent substance, like hydrogen or silver, is found to be 9649·4 coulombs, or absolute electro-magnetic units; but this is obviously equal to Ne where N is the number of molecules in a gramme-molecule, and e is the value of the electron in electromagnetic units. Hence, as soon as e had been accurately determined N could be at once computed with precisely the same degree of precision obtained in the measurement of e. N is thus found to be $6\cdot 062\times 10^{23}$. This number of molecules in a gramme-molecule is usually called the Avogadro number. From it we determine at once the number of molecules in a cubic centimetre

of any gas, or, indeed, the exact number of molecules in a given weight of any substance whatever of known molecular weight, so that our knowledge of practically all absolute atomic and molecular magnitudes comes from the evaluation of *e*. The same is true to a somewhat lesser extent of atomic dimensions and of radiation constants. Thus, *e* takes its place as a constant of outstanding practical and theoretical importance. All electrical currents are caused by the slow travel of a well-nigh infinite number of these electrons along the wire which carries the current. All light or other short wave-length radiations are caused by changes in positions of electrons within atoms. All atoms are built up out of definite numbers of positive and negative electrons. All chemical forces are due to the attractions of positive for negative electrons. All elastic forces are due to the attractions and repulsions of electrons. In a word, *matter itself is electrical in origin.*

ELECTROPHONE, a musical instrument making use of electric bells and giving a brilliant metallic sound, invented by the Dutch composer Daniel Ruyneman, who has employed it in some of his compositions.

ELECTROPHORUS, an instrument invented by Alessandro Volta in 1775, by which mechanical work is transformed into electrostatic charge by the aid of a small initial charge of electricity. In one form it consists of a disk of non-conducting material, such as pitch or resin, placed between two metal sheets, one being provided with an insulating handle. For the pitch or resin may be substituted a sheet of glass, ebonite, indiarubber or any other good dielectric placed upon a metallic sheet, called the sole plate. The method of use of the electrophorus is described in the article ELECTRICITY.

ELECTRO-PLATING, the art of depositing metals by the electric current. In the article ELECTROLYSIS it is shown how the passage of an electric current through a solution containing metallic ions (electrically charged atoms of a metal) involves the deposition of the metal on the cathode (the negative electrode). Under certain conditions, however, the metal is deposited in a non-adherent and pulverulent form. The main factors which influence the nature of the deposit are the following: chemical composition and temperature of the electrolyte, current density, concentration and circulation of the electrolyte, and the nature of the metal receiving the deposit (Watts, *Metal Indust.*, 1913). As the durability of the electro-deposited coat on plated wares of all kinds is of the utmost importance, the greatest care must be taken to ensure its complete adhesion. This can only be effected if the surface of the metal on which the deposit is to be made is chemically clean. If the surface is coated with rust or oxide, a preliminary cleaning is given by a sandblast or wire brushes, if the size of the object allows. Grease is removed by dipping into a hot alkaline solution. The last traces of oxide are dissolved and a bright metallic surface produced by means of a "pickling" solution, which is generally acid and varies with the metal treated. A cleaning treatment, which can generally be employed very advantageously, is to join the article as cathode in a suitable electrolyte, when the gas evolution removes much of the scale or grease mechanically.

General Methods.—The vats for depositing are generally wooden, lead-lined vessels, but may be enamelled iron, slate or particularly for small sizes, glazed earthenware. Large objects are suspended in the tanks by hooks or wires, the position of support being occasionally displaced so as to avoid wire-marks. Small objects are often heaped together in perforated trays or ladles, the cathode connecting-rod being buried in the middle. These require constant displacement since the objects are in contact at many points, and the top ones shield those below from the depositing action of the current. Processes have been devised in which the objects to be plated are suspended in revolving drums between the anodes, the rotation of the drum causing a constant renewal of surfaces, and at the same time imparting a burnishing action. As a galvanic deposit must be regular, tenacious, and usually capable of a high polish, its crystalline structure should be fine and as even as possible. With some metals, like nickel and iron, such deposits can be obtained from simple salt solutions. With others, like silver and lead, coarsely crystalline deposits are produced from such solutions, whilst finely grained deposits may generally be obtained by using electrolytes in which the metal is mainly present in the form of a complex ion. Solutions which would deposit their metal on the metal to be coated by simple displacement on immersion should not generally be used, as the resulting deposit is usually non-adherent. For this reason the acid copper bath is not used for iron or zinc objects, but is replaced by one containing copper cyanide or oxide dissolved in potassium cyanide. The formation of the complex ions reduces to a very high degree the concentration of the free metal ions, and, in accordance with the Nernst relation (*see* ELECTROLYSIS), the potential required for deposition is considerably raised; and the separation of the metal by simple displacement is precluded and is only brought about by secondary chemical interaction with some more electro-positive element, such as sodium or potassium, the ions of which are present in much larger numbers and are first separated.

Processes to Secure Regular Deposition.—It is found that an adherent, smooth, fine grained deposit is more readily obtained from concentrated solutions. Consequently, the current density should be kept low, in general about 0·02 amp. per sq.cm. (or 20 amp. per sq.ft.), because otherwise the concentration of the electrolyte is too rapidly decreased in the neighbourhood of the cathode. A high temperature and stirring also helps to prevent a decrease in concentration near the cathode. When possible the electrolyte should, as a general rule, be kept slightly acid, to prevent precipitation of basic salts or hydroxides at the cathode. The character of the deposit is frequently improved by the addition of a small quantity of an organic colloid to the electrolyte.

Hydrogen overvoltage is an important factor in the electrolytic deposition of metals. Although the separation potentials of zinc and cadmium from their solutions are higher than that of hydrogen, these metals can be deposited electrolytically before the hydrogen from a solution containing hydrogen ions; whilst iron, which has a lower separation potential than either metal, cannot. This is because the liberation of hydrogen is prevented by the high hydrogen overvoltage of zinc and cadmium, while iron has a very low hydrogen overvoltage.

A consideration of much practical importance in electro-plating is the so-called *throwing power* of the electrolyte. With an object of irregular shape there is a tendency for a thicker layer to be deposited on parts of it which project towards the anodes, whereas in hollows and indentations very little metal may be deposited. With some solutions, however, under suitable conditions, this unevenness of the layer on different parts of the surface at different distances from the anode is very small; such a solution is said to possess good throwing power. The factors which determine this important property have recently been elucidated by Arndt and Clemens (*Chem. Zeit.*, 1922) and by Haring and Blum (*Trans. Amer. Electrochem. Soc.*, 1923).

In some instances a screening or vignetting of the surface of the cathode is employed to increase the regularity of the deposit, or specially shaped anodes are employed in order that the distance between the electrodes may be fairly uniform. Supplementary anodes are sometimes used in difficult cases of this kind. With large metallic external surfaces use is sometimes made of a brush which is constantly wetted with the electrolyte while the hairs or bristles are connected with a wire anode and is painted slowly over the surface of the metal to be coated, which is connected to the negative pole of current supply.

Under these conditions electrolysis of the solution in the brush takes place. Iron ships' plates have been coated with copper in sections (to prevent adhesion of barnacles) by building up a temporary trough against the side of the ship, making the thor-

oughly cleansed plate act both as cathode and as one side of the trough. Decorative plating-work in several colours (*e.g.*, "parcel-gilding") is effected by painting a portion of an object with a stopping out (*i.e.*, a non-conducting) varnish, such as a copal varnish, so that this portion is not coated. The varnish is then removed, a different design stopped out, and another metal deposited. By varying this process, designs in metals of different colours may readily be obtained.

Special Methods.—Reference must be made to the text-books (*see* ELECTRO-CHEMISTRY) for a fuller account of varied solutions and methods used for electro-plating with different metals.

For the deposition of zinc, Sherard Cowper-Coles devised a process in which a lead anode is used, and powdered zinc is suspended in the solution to maintain the proportion of zinc in the electrolyte, and so to guard against the gradual acidification of the bath. It was formerly considered essential for the satisfactory deposition of zinc to avoid the presence of any considerable amount of acid. In a process developed by Tainton and Pring, however, it has been established that the deposition of zinc either for plating or for recovery from solutions of ores can be efficiently conducted in solutions containing as much as 20–25% free sulphuric acid. This is effected by the use of current densities as high as 100–500 amp. per sq.ft. and the presence of small amounts of a suitable colloid.

Cobalt is deposited by a method analogous to that used for nickel. Platinum, palladium and tin are occasionally deposited for special purposes. In the deposition of gold the colour of the deposit is influenced by the presence of impurities in the solution; when copper is present, some is deposited with the gold imparting to it a reddish colour, whilst a little silver gives it a greenish shade. Thus so-called coloured-gold deposits may be produced by the judicious introduction of suitable impurities. Even pure gold, it may be noted, is darker or lighter in colour according as a stronger or a weaker current is used. The electro-deposition of brass—mainly on iron ware, such as bedstead tubes—is now very widely practised, the bath employed being a mixture of copper, zinc and potassium cyanides, the proportions of which vary according to the character of the brass required, and to the mode of treatment. The colour depends in part upon the proportion of copper and zinc, and in part upon the current density, weaker currents tending to produce a redder or yellower metal. Other alloys may be produced, such as bronze or German silver, by selecting solutions (usually cyanides) from which the current is able to deposit the constituent metals simultaneously.

Electrolysis has in a few instances been applied to processes of manufacture. For example, Wilde produced copper printing surfaces for calico printing-rollers and similar articles by immersing rotating iron cylinders as cathodes in a copper bath. Elmore, Dumoulin, Cowper-Coles and others have prepared copper cylinders and plates by depositing copper on rotating mandrels with special arrangements. Cowper-Coles was also successful in producing true parabolic reflectors for projectors by depositing copper on glass surfaces.

The most noteworthy recent developments in electro-plating are in the deposition of iron and chromium and the use of electroplating for restoring worn components.

Iron Plating.—Processes of iron plating have been applied mainly at Grenoble and in the United States (*Trans. Amer. Electrochem. Soc.*, 1924) for the direct formation of articles such as boiler tubes of soft iron which on account of its purity has special properties.

In the process of Boucher in operation at Grenoble, which is used for producing iron tubes, an electrolyte is employed consisting of ferrous sulphate or ferrous chloride solution. The electrolyte is, during use, circulated over iron turnings and air is also blown in or iron oxide added. In this way the hydrogen ion concentration is kept low, and the dissociated air tends to depolarize the discharge of these ions. The current density is 10–11 amp./dm^2 and the temperature about 80° C. The small hydrogen content of the metal is eventually removed by annealing at 900° C. The product contains 99·97% iron. About 4 kw. of current are required for one kilo of iron deposited.

Chromium Plating.—Chromium plating has been largely developed very recently for special purposes where surfaces are required which possess the highest possible resistance to abrasion. Chromium deposits can be produced which are considerably harder than the hardest steel. The main application has so far been in the surface coating of plates used in intaglio printing which are subjected to severe abrasion during use. Formerly these plates were made of case-hardened steel or nickel-plated. A procedure now adopted is to deposit a thin layer of chromium on the nickel surface of the finished printing plate (*Chem. and Met. Eng.*, 1925). The thickness of the deposit need not exceed 0·0002 in. (0·005 mm.) in order to yield a greatly increased service. It is found that as a result of the poor throwing power in chromium plating, the lines are made deeper and the impressions are better than from the original plates. A smooth bright deposit is essential as subsequent polishing is impracticable. Further, after the chromium plate has been worn almost through it can be "stripped" and a new surface deposited, without any loss of definition. The electrolyte employed is usually a solution of chromic acid with a small amount of chromic sulphate and chromium carbonate. The chromium carbonate neutralizes any excess acid and maintains the correct degree of acidity or hydrogen ion concentration which is essential for the deposition. The current density employed is 100 to 200 amp. per sq. foot (11 to 22 amp. per sq.dm.), voltage, 7·9, and temperature of bath 40°–50° C.

Repair of Worn Components by Electro-deposition.—An important application of electro-deposition which has been made in recent years is to the restoration of worn parts such as the bearings of machines, wheel axles and the linings of guns and howitzers (J. P. McLare, *Trans. Faraday Soc.*, 1924–25). Copper was applied at the outset for this purpose on account of ease of deposition, but it is not sufficiently hard for a rubbing or rolling bearing surface, and even when used merely as a "packing," its liability to extrude under pressure renders it unsuitable for use. Methods of depositing iron have subsequently been developed. Formerly it was only possible to obtain this in coherent layers of a maximum thickness of about 0·003 in. and a procedure was adopted which employed alternate thin layers of copper and iron. It was found that one of the main causes of the inability to obtain thick deposits of iron was the lack of adequate preparatory cleaning of the metal surface. Eventually the adoption of an anodic system of cleaning in an acid bath, following a prolonged immersion of the articles in a boiling caustic soda solution, has enabled the development of a process whereby deposits of iron or nickel of any desired thickness may be applied.

The initial cleaning of the metal surface to be coated is effected by connecting as cathode and suspending in a hot electrolyte containing 1 lb. of commercial caustic soda, ½ lb. of washing soda, and 1 oz. of sodium cyanide per gallon of water. A current density of about 100 amp. per sq.ft. of cathode surface is applied and electrolysis continued for a period of from 3 to 10 minutes. The parts to be protected from deposition are then insulated by coating with a suitable wax composition and the metal is given a further anodic cleaning treatment for a short period in a cold alkaline cleaning bath. The object is then rinsed in clear cold water and transferred to an acid cleaning bath containing 2¼ lb. of sulphuric acid in 1 gal. of water, and by connecting as anode is subjected to an electrolytic current of at least 200 amp. per sq. foot. On applying the current a black film forms on the metal immediately and very little gas is formed; in about 30 sec. or so, however, the film is observed to break away and a free evolution of oxygen occurs. The gassing is allowed to continue for about 20 sec. when the surface of the article is seen to have a clear grey matte appearance. The acid is then washed off as rapidly as possible and the article transferred to the depositing tank. In some instances, as with the harder steels, the black film does not break away completely. In this event, the current is reversed for about a minute, making the article the cathode; an evolution of hydrogen then takes place which assists in disintegrating the clinging film, and on again reversing the current the cleaning is completed. The metal, after rinsing with water, is then transferred rapidly to the electro-deposition bath. The electrolyte

formerly considered essential consisted of a dilute solution of neutral ferrous ammonium sulphate. With this bath, a current density not exceeding 5 amp. per sq.ft., agitation of the solution, and a mechanical means of removing clinging hydrogen bubbles from the deposit to prevent pitting were essential. It has subsequently been found possible to employ concentrated solutions, containing from 3 to 3½ lb. of ferrous ammonium sulphate per gallon, and a current density of 18 to 20 amp. per sq.ft. without the necessity for continuous agitation of the electrolyte. The concentrated solution should be neutral or only very slightly acid to obtain deposits of reasonable hardness. The anodes consist preferably of very soft Swedish iron wire, wound in the form of a cylinder on flat grids. The temperature should be maintained at about 18° C.

Thick deposits of nickel are obtained from an electrolyte containing 2 lb. nickel sulphate, 3¼ oz. nickel chloride, and 4¾ oz. boric acid per gallon of water. A current density of 20 amp. per sq.ft. of cathode surface can be employed at normal room temperatures, giving a rate of deposition of approximately 0·001 in. of thickness per hour. As with iron, good deposits free from pitting can be obtained without the necessity for agitation when a sufficiently large bulk of liquid can be accommodated around the work.

(J. N. P.)

ELECTROSCOPE, an instrument, as its name indicates, for detecting electrification. (*See* ELECTRICITY: *Faraday's Works on Electrostatics* and INSTRUMENTS, ELECTRICAL: *Electrostatic.*)

ELECTROSTATICS, the study of phenomena associated with stationary electricity. (*See* ELECTRICITY: *Electrostatics.*)

ELECTROTHERAPY, a general term for the use of electricity in the alleviation and cure of disease. Many claims have been made for it in the past which could not be justified, or at best were psychological. Of recent years its sphere has been better defined and at present four different types of electricity are employed in medicine:—

(1) The constant, continuous, or galvanic current.
(2) The interrupted currents of low frequency (the interrupted galvanic current, the alternating and sinusoidal currents, the faradic current).
(3) The interrupted currents of high frequency (high frequency currents and diathermy).
(4) The high voltage unidirectional currents derived from the static machine.

The Constant Current.—It is now generally accepted that the chief curative action of the constant current is due to the reflex action resulting from the stimulation of the cutaneous and subcutaneous nerves immediately beneath the area over which the pads conveying the current are applied. By this reflex stimulation an increased blood supply, with its valuable consecutive effects, is obtained. This stimulation is very similar in nature to what has been termed "counter-irritation," with the great advantages that the amount of stimulation is capable of exact regulation, that it takes place within the epidermis, thus acting directly on the nerve endings, and that it can be continued daily for a long period, improving the condition of the skin rather than destroying it, as the constant painting on of an irritant would do. The extent of this stimulation is dependent on the strength and duration of the current employed and the nature of the solutions with which the conducting pads are moistened.

When a positive pole of zinc or copper, or when salts of these metals in solution are employed, a caustic and destructive compound such as the chlorides or oxychlorides of zinc or copper is formed in the submucous or subcutaneous area by the combination of the negatively charged atoms of zinc (zinc ions), proceeding from the positive pole to the tissues, with the positively charged chlorine atoms (chlorine ions) proceeding from the tissues toward the positive pole. In the process of combination the atoms get rid of their electrical charges, the process is therefore rather one of de-ionisation. This method is very valuable for the thorough and safe destruction of the diseased membranes of cavities, such as the unhealthy mucous membrane of the uterus or the lining of septic cavities.

Similarly, by the employment of less destructive solutions, a reflex stimulation of the tissues can be brought about. The amount of stimulation depends on (1) the nature of the solution; (2) the strength and duration of the current. In general the best results are obtained by a solution causing the minimum of irritation and the application of the maximum current which can be readily tolerated by the patient for at least 40 minutes.

This form of treatment is indicated when increased local nutrition or the re-absorption of fibrotic thickening is desired: such as in the local treatment of chronic rheumatics, neuritis, sprains, and many other conditions. It is especially valuable in the treatment of tic douloureux, for which the employment of strong currents of from 40 to 80 milliamperes is necessary.

Interrupted Currents of Low Frequency.—The therapeutic effects obtainable from the employment of the interrupted currents of low frequency have been greatly increased by the methods recently introduced by Prof. Lapicque, Prof. Leduc, and Dr. Morton Smart. In the method of Lapicque, by the interposition in parallel of condensers with capacities varying from 2 to 30 microfarads, an interrupted current of such progressive onset and decline is obtained that it will excite contractions in paralysed muscles without exciting corresponding or over-powering contractions in the neighbouring healthy muscles due to the physiological fact that the contraction excited in a paralysed muscle is less dependent on a sharp make and break than with a healthy muscle.

In the treatment of infantile paralysis objection has been raised to the electrical excitation of the paralysed muscles on account of the over-excitation of the opposing healthy muscles which accompanies such stimulation. By the method of Lapicque this objection is entirely overcome. The defined and isolated contraction elicited by this method has a valuable re-educative effect in cases of recovering motor-nerve lesions. Lapicque's technique is especially useful in the treatment of facial palsy.

The Leduc current consists in the interruption at a frequency of about 100 per sec. of the galvanic current at the very low intensity of from two to four milliamperes. Leduc claims that it is possible by employing these minute currents interrupted at such frequency to induce successively local anaesthesia and, if applied through the brain, general anaesthesia, electric sleep, coma, and eventually death. Applied locally, avoiding the region of the brain, this treatment is perfectly safe and has proved valuable in the treatment of certain forms of neuritis and especially in that otherwise intractable condition, causalgia.

The advantages of the instrument and technique elaborated by Dr. Morton Smart for the application of faradism to muscles deficient in excitability and tone, which have very greatly enhanced the therapeutic value of the faradic current, are that the pain of the treatment is abolished or reduced to a minimum, the vigour and amplitude of the contractions are increased; and, above all, when employing this method, the operator can at once appreciate when the muscles are becoming fatigued and so can at once discontinue further stimulation before any of the bad effects, which were liable to occur when employing the older methods, can take place.

High Frequency Currents and Diathermy.—Although the researches of D'Arsonval which led to his discovery of the high frequency currents and diathermy were commenced in 1888 and concluded in 1890, diathermy (the most valuable result of his research) only began to be employed in Great Britain in 1911 or 1912. D'Arsonval, when experimenting with alternating currents in 1888, noticed that, with a constant strength of current, the more rapidly the interruptions occurred the more vigorous were the resulting muscular contractions.

When, however, a frequency of from 2,500 to 5,000 excitations a second was reached, a decrease in the vigour of the contractions occurred and progressively decreased with the increased frequency of excitation. At this time, the instruments at D'Arsonval's disposal did not permit a further increase of frequency, but in 1890, by employing the wireless apparatus of Hertz, he obtained what he rather exaggeratingly termed "billions of oscillations a second."

With these frequencies he found that he was able to pass a current of two or three amperes through the human body without producing any muscular contraction or other sensation than that of heat. He thus obtained the clinical high frequency currents. Diathermic currents were subsequently evolved from the high frequency currents by such modifications in the instruments as permitted currents of lower voltage, higher amperage, and higher frequency to be obtained.

The main therapeutic effect of diathermy is the generation of heat deeply in the tissues by the friction from the oscillation of the electrically charged atoms. Any organ of the body, any limb or part of the body, or the whole body to any extent required, can be heated by this current. Before the advent of diathermy we were able to heat only the superficies or the accessible cavities of the body; even under such limitations the application of heat formed one of the oldest and most useful therapeutic measures. Moreover, the heat obtainable from diathermy admits of exact and easily regulated adjustment to a degree never before obtainable.

The consecutive effects of heat applied in this manner are an increased blood supply, relaxation of tension and spasm with consequent relief of pain, increased local drainage, increased local nutrition. The heat thus generated is an expression of the mechanical or dynamic force exercised by the oscillations of the ions within the tissues and this primary action (the so-called "ionic massage") appears to be of value in aiding the dispersal of recent effusions. Some of the main indications for the application of diathermy are the relief of pain and spasm, the treatment of rheumatism, neuritis, sciatica, asthma, and pneumonia.

Diathermy in Surgery.—Apart from its medical application, diathermy is of considerable value in surgical practice for the destruction of superficial morbid growths, such as rodent ulcers, warts, naevi, etc. When applied for this purpose, in place of the two electrodes of large size employed in medical diathermy, one large (the indifferent electrode) and one small metal point (the active electrode) are substituted. In this way the heat, which is distributed and is only appreciated as a slight warmth over the large pad, is concentrated at the small metal point and almost immediately coagulates and destroys the tissue with which the point is brought in contact. Very satisfactory results have been obtained from the treatment of haemorrhoids in this manner.

The point of a metal wire can be employed as the active electrode and by inserting this wire through, *e.g.*, a cystoscope (an instrument for viewing the interior of the bladder) small growths can be readily destroyed and serious surgical operations avoided.

High Voltage Unidirectional Currents.—The therapeutic effects obtainable from the static machine were exhaustively worked out towards the end of the 19th century, notably by Drs. W. J. Morton and Benham Snow of New York. Recent research has enabled the therapeutic action of the currents derived from these instruments to be rationally explained on a physiological basis and the claims formerly put forward for this form of treatment have been fully justified. Under their influence the regularity and frequency of the pulse are increased, the blood pressure is raised, and skin action is promoted. The nervous system is quieted, sleep is better, and the patient often becomes drowsy during the application. (W. T.)

ELECTROTYPING, the production of copies of types, wood-cuts, medals and other objects by means of the electro-deposition of a metal upon a mould. A negative cast of the object to be copied is generally prepared in the first place, and is made from gutta-percha, plaster of paris, or wax. After being coated with a thin layer of graphite to serve as conductor the negative cast is connected to copper leads and is immersed in an electroplating bath as cathode. Forms of fusible metal may also be used, or electro-deposition may be effected on mandrels of special shapes and later stripped off.

Electrotypes may consist of copper, nickel or iron, the first metal being most usually employed. Copper electrotypes which are subjected to much wear are often "faced," however, with a thin coating of nickel, iron or chromium. In producing the relatively thick deposits of copper required in electrotyping an acid copper sulphate bath is used, similar to that employed in refining. The electrolyte contains 200 grams $CuSO_4,5H_2O$ and 30 grams H_2SO_4 per litre, and is usually kept somewhat above room temperature. The anodes are sheets of electrolytic copper. The current density is about 2 amp./dm.^{2} and the bath voltage about one volt. For more rapid working the temperature is raised and the electrolyte stirred by vigorously blowing in air. In this way current densities of 5–8 amp./dm.^{2} can be employed at the cost of a considerably increased bath voltage. When the copper positive is sufficiently thick and rigid, the whole is taken from the bath, the negative cast detached, and the electrolyte backed with some low melting lead alloy to provide the necessary strength.

Other applications of electrotyping are in the Elmore process, by which seamless copper tubes are produced. The density, regularity and evenness of the deposit are increased by continuously rotating the cathode and by causing pieces of agate, pressed on the cathode surface by springs, to travel continuously from one end of the cathode to the other and back again. To detach the tubes subsequently from their cores, they are gently heated, and worked loose by pressure. Their great tensile strength allows them to be easily drawn; consequently a few standard sizes only are directly produced in the bath. Tubes up to 5 ft. in diameter and 16 ft. in length have been produced. In other processes, such as that devised by Cowper-Coles, a very rapid rotation of the cathode enables high current densities to be used and improves the smoothness of the deposit. The similar production of iron tubes is described under ELECTROPLATING. An ingenious process has been described (*Chem. and Met. Eng.*, 1914), for the production of narrow, flat copper tubing through which small supporting tubes pass transversely at regular intervals: the copper is deposited on a perforated lead band which passes continuously through the solution, and the lead is subsequently melted out. Finally, Thain (*Trans. Faraday Soc.* 1921), has described an interesting electrotyping operation in which copper water jackets are built up around the cylinders of aero-engines. The metal is deposited on a fusible metal form which is afterwards melted out. A preliminary coating is put on from a cyanide solution, the main deposit being produced in the acid copper sulphate bath. (*See* also ELECTROPLATING, PRINTING.)

ELECTRUM, ELECTRON, an alloy of gold and silver in use among the ancients, described by Pliny as containing one part of silver to four of gold. The term is also applied in mineralogy to native argentiferous gold containing from 20 to 50% of silver. In both cases the name is derived from the pale yellow colour of electrum resembling that of amber (Gr. ἤλεκτρον).

ELEGIT, in English law, a judicial writ of execution, given by the statute of Westminster II. (1285), and so called from the words of the writ, that the plaintiff has chosen (*elegit*) this mode of satisfaction. Previously to the statute of Westminster II. a judgment creditor could only have the profits of lands of a debtor in satisfaction of his judgment, but not the possession of the lands themselves. But this statute provided that henceforth it should be *in the election* of the party having recovered judgment to have a writ of *fieri facias* (*q.v.*) unto the sheriff on lands and goods or else all the chattels of the debtor and the one-half of his lands until the judgment be satisfied. Since the Bankruptcy Act, 1883, the writ of *elegit* has extended to lands and hereditaments only. (*See* EXECUTION.)

ELEGY, a short poem of lamentation or regret, called forth by the decease of a beloved or revered person, or by a general sense of the pathos of mortality. The Greek word ἐλεγεία is of doubtful signification; it is usually interpreted as meaning a mournful or funeral song. But there seems to be no proof that this idea of regret for death entered into the original meaning of ἐλεγεία. The earliest Greek elegies which have come down to us are not funereal, although it is possible that the primitive ἐλεγεία may have been a set of words liturgically used, with music, at a burial. When the elegy appears in surviving Greek literature, we find it dedicated, not to death, but to war and love. Callinus of

Ephesus, who flourished in the 7th century B.C., is the earliest elegist of whom we possess fragments. A little later Tyrtaeus was composing his famous elegies in Sparta. Both of these writers were, so far as we know, exclusively warlike and patriotic. On the other hand, the passion of love inspires Mimnermus. In the work of Theognis of Megara we can observe the characteristics of Greek elegy best. Here the Dorian spirit of chivalry reaches its highest expression, and war is combined with manly love. It is curious to notice that antiquity styled the funeral dirges of Theocritus, Bion, and Moschus—which are to us the types of elegy—not elegies at all, but idylls.

Gallus, whose works are unhappily lost, composed erotic elegies, which were the earliest elegies in Latin. The *Cynthia* of Propertius, however, with its rich and unexampled employment of that alternation of hexameter and pentameter which had now come to be known as the elegiac measure, seems to have settled the type of Latin elegy. Tibullus is always named in conjunction with Propertius, who was his contemporary, although in their style they were strongly contrasted. Finally, Ovid wrote elegies of great variety in subject, but all in the same form.

From the beginning of the 16th century "elegy" was used in English, as it has been ever since, to describe a funeral song or lament. The *Daphnaida* of Spenser (1591) is an elegy in the strict modern sense. Dr. Johnson's definition, "*Elegy*, a short poem without points or turns," is singularly inept and careless. By that time (1755) English literature had produced many great elegies, of which the *Lycidas* of Milton is by far the most illustrious. Since the 18th century the most famous examples of elegy in English literature have been the *Adonais* of Shelley (on Keats) and the *Thyrsis* of Matthew Arnold (on Clough). The most celebrated elegy in English is that written by Gray in a country churchyard. This, however, belongs to a class apart, as it is not addressed to the memory of any particular person. James Hammond (1716–42) enjoyed a certain success with his *Love Elegies* in which he endeavoured to introduce the erotic elegy as it was written by Ovid and Tibullus. This experiment took no hold of English literature but was welcomed in France in the amatory works of Parny (1753–1814), in those of Chênedollé (1769–1833), and of Millevoye (1782–1816). Lamartine must be included among the elegists, and his famous "Le Lac" is as eminent an elegy in French as Gray's "Country Churchyard" is in English. The elegy has flourished in Portugal, partly because it was cultivated with great success by Camoens. In Italian, Chiabrera and Filicaia are named among the leading national elegists. In German literature, the notion of elegy as a poem of lamentation does not exist. The famous Roman elegies of Goethe imitate in form and theme those of Ovid; they are not even plaintive in character.

ELEGIAC VERSE has commonly been adopted by German poets for their elegies, but by English poets never. Coleridge defines this kind of verse, which consists of a distich of which the first line is a hexameter and the second a pentameter, in the following illustration:

> In the hexameter rises the fountain's silvery column,
> In the pentameter aye falling in melody back.

The word "elegy," in English, is one which is frequently used very incorrectly; it should be remembered that it must be mournful, meditative, and short without being ejaculatory. Thus Tennyson's *In Memoriam* is excluded by its length; it may at best be treated as a collection of elegies. Wordsworth's *Lucy* is a dirge; this is too brief a burst of emotion to be styled an elegy.

ELEMENTARY EDUCATION. While elementary schools of a kind were founded before and after the Reformation (*see* SCHOOLS), the first connected movement towards providing such instruction on a large scale was that inaugurated in 1699 by the Society for Promoting Christian Knowledge, which by 1729 had led to the foundation of 1,658 charity schools with some 54,000 children. A somewhat similar impetus was provided by the Sunday School movement under Robert Raikes towards the end of the century. But the beginnings of a really national system may be said to date from the commencement of the 19th century, when Lancaster, and later Bell, established respectively undenominational and Church of England schools.

First State-aided Schools.—The first State grant was made in 1832. In 1843 State aid was given to training colleges. The pupil teacher system was established in 1846. Payment by result, and so examinations (*q.v.*) were introduced in 1862. In 1870 the first education act was framed and school boards established, to supplement but not to supplant existing church schools with schools in which religious teaching was to be undenominational.

Development of Free Education.—Elementary education was made free in 1891, and in 1898 payment by result was abolished, while during the last 20 years of the century higher-grade schools had been developed. In 1902–03 school boards were superseded as the local authorities by the county councils, who were made responsible under the act for all elementary schools in their area. Various unsuccessful attempts were made to upset the new system, as far as the church schools were concerned, in 1907–08, while during the same period medical inspection and after-care committees were instituted, and increasing stress was laid on physical training and school hygiene; the pedagogical side of the board's work had been emphasized in the *Suggestions for Teachers* (1905) and central schools established in place of the old higher-grade in 1906. Further milestones on the road of progress were the provisions for the preliminary education of the future teachers in secondary schools and the establishment of public training colleges, either locally or in the universities. Other landmarks are the Education Act of 1918, which codified and extended the schools' activities, and in particular raised the leaving age to 14, and the introduction of the Burnham scale of salaries in 1920. (C. BR.)

20TH CENTURY DEVELOPMENTS

The policy of the Board of Education as originally set out in the prefatory memorandum to the *Suggestions for Teachers*, first published in 1905, and reaffirmed in subsequent issues of the pamphlet (Ed. 2,638) indicated very clearly the ideal that animated English administrators, especially since the beginning of the 20th century.

The only uniformity of practice that the Board of Education desire to see in the teaching of public elementary schools is that each teacher shall think for himself, and work out for himself, such methods of teaching as may use his powers to the best advantage and be suited to the particular needs and conditions of the school. Uniformity in details of practice (except in the mere routine of school management) is not desirable, even if it were attainable. But freedom implies a corresponding responsibility in its use.

The administration and inspection of public elementary education upon lines as broad as these have combined with other influences to produce the variety which characterizes English and Welsh elementary schools. Other influences besides those directly exercised by the Board of Education may also be set down here.

Influence of Psychological Science.—The study of psychology has exercised a powerful and widespread influence upon elementary school teaching. For example, the emphasis placed by W. MacDougall (*Social Psychology*, 1908) and his school upon the importance of "interest" in education has been almost universally reflected in school methods and schemes of work and has been largely although not entirely responsible for many attempts—often singularly original and successful—to co-ordinate the life of the child in school with his life at home and for the adoption of "imaginative methods," *e.g.*, free drawing, dramatization, modelling, etc.

Again, teachers everywhere have taken great interest in both the theory and practice of intelligence tests (*q.v.*). The realization that the traditional methods of teaching in elementary schools often fail to develop latent ability, has led to original experiment on these lines and to a critical scrutiny of traditional examinations.

Physical Training.—The criticism of medical authorities (closely associated with the development of the school medical service) has checked any tendencies to regard education as an exclusively intellectual process. The modern elementary school has an equal regard for the physical as for the mental development of its pupils, and, quite apart from the specifically remedial

action of the school medical officers, now does much to improve the physique of its children. (*See* PHYSICAL TRAINING.) Considerable time and attention are devoted to suitable games (largely musical in character) in the infants' schools; and organized games, such as cricket, football, swimming, netball and folk dancing are practically universal in the senior schools. Progress has also been made in the provision of schools for the blind, deaf, etc. (*See* BLIND, TRAINING OF; DEAF AND DUMB, EDUCATION OF.)

Individual Methods.—The influence of Mme. Montessori's theories (*see* MONTESSORI SYSTEM) has been very marked in directing criticism against the traditional classroom methods of teaching and so leading on to a particularly fruitful experimentation in individual methods of instruction, which has been remarkably general and often remarkably successful in the infants' schools. The great majority of English infants' schools employ "individual methods" to a substantial extent, although seldom to the entire exclusion of the more traditional classroom methods. Somewhat similar methods—such as those adopted under variations of the "Dalton plan"—have been largely applied to the case of older pupils, the broad aim being to train the children to use books and to work individually with self-reliance and effect.

Teachers' Courses.—The "teachers' courses" have become more and more important in the development of elementary school teaching. The popularity of "refresher courses" for teachers already fully qualified increased steadily after the World War, and these courses are now attended by thousands of teachers annually. (*See* SUMMER SCHOOLS.) The courses may be held during the school holidays or the school terms; they may take the shape of continuous fortnights of study or of weekly demonstrations and lectures; they may be conducted by a local education authority, the Board of Education or private enterprise; they may deal with the theory or practice of education, or aim merely at deepening the teachers' knowledge of a particular subject. But whatever their system they have exerted a very beneficial influence upon elementary school teachers.

Special Developments.—Provision for the advanced education of children capable of profiting by it has been made. The brighter children are drafted away in increasing numbers from the elementary schools at the age of 11–12 to continue, by means of scholarships and free places, their education in the secondary schools. There has been an increase in many areas of "central schools," "central classes," "higher tops" and distinctively vocational schools, which also draw their pupils from contributory elementary schools, generally on a selective basis. Thus more and more the children remaining in the elementary schools beyond the age of 12 are those that are left after the cream has been drawn off, and the elementary school is left to solve the problem of a suitable method of education for children not of the first ability. The solution of this problem is dealt with in the paragraph below on the education of the adolescent.

Relations with Parents.—The elementary school as a whole since 1910 has very definitely resisted any tendency to become an educational machine for the instilling of mere information into children. Not many things are so significant as the widespread popularity of the "Education Week"—a week set apart by a local authority in order to explain and exhibit its system of education to the public. (*See* SCHOOL AND THE HOME.)

Infants' Schools.—As regards the infants' school, the special aim here is, not only to impart a rudimentary educational grounding, but to develop interest and the natural activities, special weight being laid upon oral responsiveness. The lively, eager, interested child, although with the powers of concentration proper to his age, is increasingly regarded as the typical product of the good infant school.

Senior Schools.—In the senior schools the general aim is to train the child in habits of independent work and self-reliance and to cultivate in him an interest and ability in intelligent work, which will stand him in good stead long after leaving school. In particular, the position of arithmetic as the weightiest subject in the elementary school curriculum has been severely shaken, if not definitely occupied by English, which has made great advance. The old multiplicity of subjects has defined itself into two groups—the English group, including reading, spelling, compositions, the study of elementary literature, geography and history; and the mathematical-scientific group, including arithmetic, elementary mathematics and general science. This process of definition, with its accompanying simplification of the whole and co-ordination of parts, has done a great deal to liberalize both the content and method of teaching.

Handwork.—Handwork has established itself firmly as a teaching method; as a subject in the shape of laundry, cookery and housewifery for girls, and wood, metal and varied work for boys, its value is increasingly allowed, especially for the kind of children likely to remain in the elementary schools until their school-life finishes. (*See* SCHOOL AND ITS CURRICULUM.)

Education of the Adolescent.—The most important event in the development of English public education was undoubtedly the issue of the *Report on the Education of the Adolescent* (1926), by the consultative committee of the Board of Education. This report, rich in educational material and suggestions of all sorts, can only be summarized here. Its chief recommendations are as follows:—

(1) That primary education should be regarded as an initial stage, definitely ending in ordinary cases at the age of 11. At this point all normal children should go forward to some form of post-primary education, which preferably should be provided in premises other than those used for primary purposes.

(2) That the post-primary stage of education should include not only secondary schools, but other types of post-primary school giving a wide variety of curriculum in accordance with the interests and abilities of the children. The schools which provide post-primary education should include, besides secondary schools, the following types:—(*a*) Selective central schools, (*b*) non-selective schools, (*c*) senior classes specially organized for the purpose in primary schools, (*d*) technical and "trade" schools.

(3) That school attendance up to the age of 15 should be made obligatory by legislation at the beginning of the school year 1932.

The committee suggested that the secondary schools should in future be known as "grammar schools" and the post-primary schools (*a*, *b*, *c*) be named "modern schools"; that the education in the modern schools be planned to cover a three years', and, when possible, a four years' course, and that it should definitely be a more "realistic" and "practical" type than that obtaining in the grammar schools, while being at the same time no less humane.

The president of the Board of Education (Lord Eustace Percy) intimated that he did not consider the moment opportune for introducing legislation for extending the age of compulsory school attendance. The other recommendations of the committee, however, impressed themselves deeply upon the administration of the board and of the local education authorities. In their circular 1,350 of Jan. 1925 the board had already recognized the age of 11 as the dividing line between "junior" and "senior" education, and had stressed the need of making provision for the advanced instruction of children over the age of 11 by giving opportunities for suitable classification and organization. The need for these opportunities and for the provision of forms of post-primary instruction alternative to the secondary school was implicitly recognized in the Education Act of 1918, but the effect of the committee's report was to throw into stronger relief the problem of the provision of post-primary education and to impress its importance upon public opinion.

Definite separation of primary and post-primary education could not of course be carried out by a stroke of the pen, when the vast majority of English schools had been structurally planned in accordance with a traditional organization of an infant department for children up to about seven and senior departments for boys and girls from seven to 14; when the number of central schools or suitably organized senior schools was inadequate, and the problem was further complicated by "dual control." But the shifting or decline of population had, in many districts, set free a good deal of elementary school accommodation, and whenever such an opportunity occurred, it was seized by the more active local education authorities for a comprehensive reorgan-

ization of the local schools on the lines of the report. The general drop in the number of births led to much more being found feasible in this direction than at first appeared. The lines of a further advance are outlined in the Board's Circular 1,397 of May 18, 1928. The circular laid down as the main task of the local education authorities during the years 1930–33 the solution of the closely related problems of the reorganization of the schools on the lines recommended by the Report on the Education of the Adolescent, the elimination of large classes, and the replacement, reconstruction and repair of all defective school premises. An official pamphlet entitled "The New Prospect in Education" gives more detailed suggestions on the grading and instruction of pupils above the age of 11. It will remain for experience to show which are the best of the many paths that are being tried as a means of advance through this difficult and most important territory. (*See* also EDUCATION: *England* and *Bibliography.* For elementary education in other European countries, *see* EDUCATION: *Growth of National Systems,* under the sections dealing with the separate countries. (K. M. A.)

UNITED STATES

Throughout the colonial period of American history and during the national period up to the middle of the 19th century the lowest unit of the American educational system was called the district school or sometimes the common school. The district school was not graded and was open to pupils until they reached their majority. It was supported in part by fees levied on the pupils, in part by subscription and in part by taxation. Following the reforms of Horace Mann in Massachusetts and of Henry Barnard in Connecticut and Rhode Island, that is from about 1850 on, the lower school was graded. Attendance was restricted to pupils of from 6 to 14 years. In general, throughout the northern States, the elementary school included eight grades. In a few centres in New England nine grades were included. Since the rise of the public school system in the southern States, subsequent to the Civil War, a seven grade school has been common in such States as Virginia, Texas, Louisiana, Georgia and Alabama.

Since about 1910 a strong tendency has manifested itself throughout the United States to reduce the number of grades in the elementary school to six. The higher grades which formerly were included in the elementary schools, especially the seventh and eighth, have very generally been absorbed into the so-called junior high school. This change is directly traceable to the fact that instruction has so far improved and the number of days during which pupils attend school each year has been so increased that it is now possible to cover in six grades the instructional materials which formerly required a full period of eight years.

Since the middle of the 19th century there has been a great increase in the average schooling of Americans. It is estimated that in 1840 the school attendance of the average citizen was limited to 208 days. In 1870 the number of days of attendance increased to 582, in 1890 to 770. In 1928 the average attendance of Americans was somewhat more than 1,200 days. These changes are due in part to the enactment of compulsory attendance laws in force in all the States. In larger measure, however, the changes are traceable to a growing desire on the part of parents that their children be better prepared for life in the modern world where advanced forms of knowledge are requisite to any high degree of success.

The graded elementary school is everywhere free. The annual expenditure for all public schools has increased from $1.64 per head of the total population in 1870 to $17.30 in 1926; *i.e.,* from $15.55 per pupil in average attendance in 1870 to $102.05 in 1926. The curriculum of the district and elementary school at first consisted almost exclusively of the so-called three R's, reading, writing and arithmetic. Since 1865 there has been a rapid expansion of the curriculum. History, geography, physiology, nature study, drawing, manual training, home economics and a number of other less common subjects have appeared in the programmes of more progressive schools, until the merging of the upper grades into the high school through the organization of the junior high school.

The expansion of the elementary curriculum has been accompanied by a demand for increased training of teachers. In the period of the district school the teacher was elected by the town meeting or was chosen by the lay officer elected as a trustee of the district. His or her training was often meagre and never included special professional preparation. With the rise of State boards of education in 1837 the practice of certificating teachers through the central State educational authorities has become common. All States restrict the local district officers in their choice of teachers to persons thus certificated. The States have also organized normal training schools (*q.v.*), or teachers colleges as many of them have designated themselves, where teachers may receive a professional training. The first State normal school was established in Massachusetts in 1839. In 1926 there were 400 such institutions with a total enrolment of 294,064. The more progressive elementary schools require teachers to have completed a high school education and to have taken in addition at least two years of training in a normal school. The less progressive schools, especially the one-room schools in rural districts, are often unable to employ normal trained teachers. It is estimated that from 25% to 40% of the rural teachers of the United States are without even a high school education.

The school buildings in which elementary schools are now housed are vastly more commodious and hygienic than were the buildings which housed the district school. These improvements are in part due to the fact that the rise of urban communities has made it possible to concentrate pupils in such numbers in a single building that the building can be provided with facilities which were out of the question in small schools. It is true, however, that even in the rural districts there has been a vast improvement in the construction and equipment of buildings. The Bureau of Education supplies figures which indicate the improvement since 1870. At that date the total value of school property was $130,383,008. In 1900, when the population of the United States was approximately twice the population of 1870, the value of school property had increased to $550,069,217. In 1926, when the population was about three times that of 1870, the value of school property was $4,676,603,539.

Attendance in elementary schools is made compulsory in all States. The first modern compulsory attendance law was passed in 1852 by the Commonwealth of Massachusetts. The last States to enact such laws were Georgia in 1916 and Mississippi in 1918. The earliest laws were at first inadequately enforced. It was not until the '80s that enforcement was vigorously carried on and then only in the older New England States, especially in Connecticut. Since 1900 there has been a movement to increase the age up to which pupils are required to attend school. Idaho requires attendance to 18 years of age, and 15 of the older States require attendance to 16. Compulsory attendance legislation is very commonly coupled with legal restrictions of employment of children. For some years the tendency has been to extend the period of education downward. The kindergarten was introduced into certain public school systems, notably in St. Louis, as early as 1873. Since then it has spread slowly until it enrolls (1927) 673,231 pupils, or between one-fifth and one-sixth as many as are enrolled in the first grade. A number of centres of investigation have laid great emphasis on the importance of the pre-school years in the formation of character, especially on the determination of emotional trends. As a result a number of pre-school training classes have been established in which controlled training of very young children is undertaken.

In the form of their organization and control American elementary schools are in sharp contrast with European schools of like level. In America the elementary schools are attended by pupils of all social ranks and they lead directly into the high school. Any pupil who completes the work of the elementary school may pass into the upper school. The administrative control of schools in the United States is largely in the hands of local authorities. The State exercises certain general powers, but these powers are, for the most part, such as to leave the local authorities much latitude of choice. For example, as stated, State departments grant teaching certificates, but the local authorities choose

the teachers for the schools from among the total list of possible candidates. There is in the United States no federal control of education, while in Europe every nation has a minister of education with large powers. The result of local control is that great variations appear, first, in the support provided for schools by different communities, second, in the quality of instruction, and third, in the breadth of the curriculum.

The total enrolment of pupils in all public schools in the United States in 1926 was 24,741,468. Of this number 20,039,051 were in elementary schools. The percentage of pupils enrolled in public schools as compared with the total population from 5 to 17 years of age was in 1926, 82·3%. The total number of school officers in public schools, including supervisory officers and teachers, was 831,078, of which number 644,631 were teachers in elementary schools. The total expenditure for public education in 1926 was $2,026,308,190, of which amount somewhat more than half, or $1,100,316,674, was for supervisory and instructional salaries.

ELEMENTS, in theoretical astronomy, the six numerical quantities used for the computation of the position of a planet. Two depend on the geometrical properties of the orbit, *i.e.,* its semi-major axis and its eccentricity. Two define the position of the plane of the orbit; one of these is the angle between the *line of nodes,* and some fixed line, the other being the inclination of the plane of the orbit to the fundamental plane. The fifth is the position of the pericentre; and the sixth, the position of the planet in the orbit at a given moment. A seventh is the time of the revolution of the body in its orbit, called its period; but the seven elements are so related that any six only have to be known in order that the seventh may be deduced. (*See* also ORBIT.) For a definition of a chemical element *see* ELEMENTS, CHEMICAL. *See* also TRANSMUTATION OF ELEMENTS. For Euclid's *Elements see* EUCLID.

ELEMENTS, CHEMICAL, are entities which have hitherto resisted analysis and which are therefore regarded as simple substances. In ancient and mediaeval philosophy, the elements were the four simple substances, earth, air, fire and water, of which all material bodies were supposed to be compounded. In pre-scientific chemistry, the elements were variously enumerated, the usual number being five or six, such as spirit, salt, sulphur, water and earth, or water, oil, air, salt and earth. The modern use of the word dates from the time of Robert Boyle (1661), who described elements as primitive and simple, or perfectly unmixed bodies, which are not made of any other bodies or of one another. From this time onwards the term element was reserved for material substances, and by the end of the 18th century the question of which are true elements had been largely settled. Early chemistry was chiefly concerned with the preparation and description of chemical substances, and no criteria were available to decide whether substances were elements or compounds. About the middle of the 18th century, however, chemistry became definitely a quantitative science based on weighing, and the criteria became available. As the weight of a compound is the sum of the weights of its elements, an element is necessarily lighter than any of its compounds. An element is therefore a chemical substance which, by being changed into other chemical substances, invariably increases in weight. By means of this rule and the experimental chemical evidence relative thereto, A. L. Lavoisier in 1789 was able to compile the first scientific list of elements.

According to the knowledge of his time he regarded the alkalis as elements, although he remarked that they were rather similar to certain oxides, and therefore might possibly contain oxygen; the truth of this was proved at a later date by Humphry Davy. But the inconsistency of the reformer may be observed with the French scientist. He included "heat and light" in his list of elements, although he knew that neither of them had weight and that neither filled his definition of an element.

However an element be defined there is always one anomaly, in that there can exist more than one chemical substance containing one and the same kind of atom. On electrolyzing water, the component hydrogen atoms are set free at one electrical pole and the component oxygen atoms at the other pole. The oxygen atoms, however, do not appear as such, but combine with one another in two different ways to form two different chemical substances, both of which are gases containing nothing but oxygen atoms. These substances are ordinary oxygen gas, composed of two atoms per molecule, and ozone, composed of three atoms per molecule. There are thus three different things which are all strictly within the definition of the element, viz., single oxygen atoms, diatomic oxygen molecules, and triatomic oxygen molecules. This anomaly in nomenclature arises from the fact that the element oxygen was identified long before the possibility was considered that elements consisted of atoms capable of various combinations to yield different chemical substances. Usually, however, no confusion arises, because in the discussion of chemical elements the atom is understood, while in the discussion of elementary substances the polyatomic molecules are implied.

When an element can exist in more than one modification, it is said to exhibit allotropy (*q.v.*), the different forms or chemical substances being termed allotropes or allotropic modifications of the element. The conception of elements is further complicated by the fact that radioactive chemical substances are known which are absolutely identical in all chemical and physical properties save those of radioactive origin and disintegration. To these substances F. Soddy in 1911 gave the name isotopes (*see* RADIOACTIVITY). In the same year Sir J. J. Thomson made the important discovery that the element neon (atomic weight 20·2) is a mixture of two atoms differing only in atomic weight, the lighter isotope having the atomic weight 20 and the heavier 22. Since then F. W. Aston, using a modification of the same method of positive-ray analysis, has shown that about half of the known elements are mixtures of atoms having whole-number atomic weights (*see* ISOTOPES).

The elements may be divided into two classes, metals and non-metals. Though the line of demarcation is not sharp, it is usual to assign to the non-metals the eleven gaseous elements, hydrogen, nitrogen, oxygen, fluorine, chlorine, helium, neon, argon, krypton, xenon and radon; the liquid element, bromine; and the nine solid elements, boron, carbon, silicon, phosphorus, arsenic, sulphur, selenium, tellurium and iodine. All the remaining elements are metals, and with the exception of mercury, which is liquid, are solids.

The number of elements is limited. Reference to the periodic classification (*q.v.*) shows that only 92 elements up to the heaviest, uranium, can possibly exist. Of these, 90 are now known, though three of them, masurium (43), illinium (61) and rhenium (75), are only known with certainty from distinctive lines in their X-ray spectra, their atomic weights having not yet been ascertained. The two missing elements are a halogen (85) and an alkali metal (87). These numbers, which relate to the order in the classification, and to the numbers of electrons in the atoms, are known as atomic numbers (*q.v.*). Elements are thus characterized not only by distinctive physical and chemical properties but by numbers indicating that they differ in structure by one electron in successive atoms in the periodic classification.

Only about 30 elements occur in nature in the free state on the earth (*see* Table II.), though it is probable that in the sun and the hotter stars all elements are present in the uncombined condition. The commonest of these earth elements, namely, oxygen, comprises free and in combination about half the weight of the earth's crust, while the rarest, radon, probably amounts to less than a million millionth of the earth's atmosphere. Table I. gives the average composition of terrestrial material half a mile deep, including the earth's crust, oceans and atmosphere.

TABLE I.

Element	Parts per 1,000	Atoms per 1,000	Element	Parts per 1,000	Atoms per 1,000
Oxygen	500	538	Carbon	1·9	2·9
Silicon	257	159	Phosphorus	1·1	..
Aluminium	73	47	Sulphur	1·1	..
Iron	42	13	Barium	0·9	..
Calcium	32	14	Manganese	0·8	..
Sodium	24	17	Strontium	0·3	..
Potassium	23	10	Nitrogen	0·2	..
Magnesium	22	16	Fluorine	0·2	..
Hydrogen	9·5	163	Bromine	0·1	..
Titanium	4·3	1·6	Remaining		
Chlorine	2·1	1·1	elements	4·5	19·4

From this table it is evident that the four light elements, oxygen, hydrogen, silicon and aluminium, comprise together about 90% of the earth's crust both by weight and by proportion of atoms, and that a dozen light elements together account for 98% of terrestrial matter.

The general properties of the elements, even of those very close in atomic weight, are extremely diverse. Carbon, for example, has a boiling point about 3,700° C, while the next heavier element, nitrogen, has a boiling point nearly 4,000° lower at −195° C, only 78° C above the absolute zero temperature of −273° C. The melting and boiling points of an element are in some cases quite close together, and in others very far apart. The boiling point of helium, for example, is only about 2° above its melting point, −271° C, the lowest temperature that has ever been attained by artificial means, whereas tungsten melts about 3,000° C and boils about 6,000° C, the highest melting and boiling points known for any element. Table II. gives the melting and boiling points, where known, for all the elements.

TABLE II.

Element	Melting point, °C	Boiling point, °C	Element	Melting point, °C	Boiling point, °C
*Helium	−271	−268·7	Radium	700	..
*Hydrogen	−258·8	−252·8	Calcium	800	1,200
*Neon	−253(?)	−245·9	Strontium	809(?)	950
Fluorine	−223	−187	Lanthanum	810	..
*Oxygen	−218·4	−182·9	*Arsenic	817	..
*Nitrogen	−210·5	−195·7	Neodymium	840	..
*Argon	−189·6	−186·1	Barium	850	..
*Krypton	−169	−151·7	Germanium	958	..
*Xenon	−140	−109	*Silver	960·5	1,955
Chlorine	−102	− 33·7	*Gold	1,063	2,530
*Radon	− 71	− 62	*Copper	1,083	2,310
*Mercury	− 38·9	356·7	Manganese	1,260	1,900
Bromine	− 7·3	58·7	Beryllium	1,290	1,900
Caesium	28·3	670	Samarium	1,350	..
Gallium	30·2	1,700	Silicon	1,434	..
Rubidium	38·5	696	*Nickel	1,452	2,340
Phosphorus	44·1	279·3	*Cobalt	1,480	2,415
Potassium	62·5	762·2	*Iron	1,530	2,450
Sodium	97·5	882·9	Zirconium	1,530	..
*Sulphur	112·8	444·7	Chromium	1,540	2,200
Iodine	114	184·4	*Palladium	1,550	3,600
Indium	155	1,450	*Carbon	..	3,700
Lithium	186	1,400	Vanadium	1,720	..
Selenium	217	690	*Platinum	1,755	4,050
Tin	231·9	2,270	Titanium	1,795	..
*Bismuth	268	1,420	Uranium	1,850	..
Thallium	301	1,700	*Ruthenium	1,900	4,150
*Cadmium	321	765·9	*Rhodium	1,907	4,000
Lead	326·9	1,525	Niobium	1,950	..
*Zinc	419·4	905·7	Boron	2,200	..
*Tellurium	450	1,400	Molybdenum	2,500	..
Cerium	623	..	*Iridium	2,550	4,400
*Antimony	630	1,440	*Osmium	2,600	4,450
Magnesium	649	1,120	Tantalum	2,910	5,500
Aluminium	658·7	1,800	Tungsten	3,000	6,000

*Elements marked thus are known to occur in the free state on the earth.

The outstanding chemical constants of the elements are their atomic weight, atomic number and valency. Atomic weights, referred to the unit of one-sixteenth of that of oxygen (taken as 16), range from 1·008 in the case of the lightest element, hydrogen, to 238·17 for the heaviest element, uranium (*see* ATOMIC WEIGHTS). Atomic weights have not yet been determined for masurium (43), illinium (61), rhenium (75), polonium (84), actinium (89) and protoactinium (91). The atomic numbers 43, 61 and 75 are known from X-ray spectra, and 84, 89 and 91 are inferred from the radioactive disintegration series. The atomic weight, 222, of the radioactive noble gas, radon (86), is not completely certain, though, by analogy with the other noble gases, it is assumed to be double the known density.

The elements may be classified into two species by the valency criterion, first, those that have no valency (the six noble gases typified by helium), and second, all the elements that possess valency (the remaining 86 elements). The valency of an element is always an integer, as follows from the law of simple multiple proportions by weight, and, as indicated by modern theory, is the number of its electrons that are effective in chemical combination. The highest known valency is eight, exemplified by the octafluoride of osmium and the tetroxides of ruthenium and osmium. It is also known from the radioactive disintegration series that the noble gas, radon, has eight electrons that are potential valency factors. According to valency, the elements fall into eight families, the eight groups of the periodic classification with valency from one to eight. For the majority of the elements, valency is not a fixed number, but varies for any one element within certain limits. This variation occurs in two different ways, some elements exhibiting variation always of two units from the maximum to a minimum, whereas others exhibit variation by a single unit. Reference to the periodic classification (*q.v.*) shows that this variation is characteristic of certain types of elements, the elements of the typical classification exhibiting variation by two units of valency, whereas the remaining 48 elements (known as transition elements) exhibit variation by one unit. All the transition elements are metals, and, with the exceptions of zinc, cadmium and mercury, have boiling points above 1,900° C. The transition elements, moreover, are the only known elements which give rise to coloured salts in their highest condition of valency, and most of them form coloured salts at every condition of valency. The valency variation of two units for the elements of the typical classification is interpreted as indicating that each atom contains one pair or two pairs of valency electrons, and that the electrons forming a pair are equally firmly bound to the atom. The valency variation of one unit for the transition elements indicates that this system of electron pairs does not exist except where the minimum valency is two. With the exceptions of copper, silver and gold, every transition element has a minimum valency of two, and thus possesses a single pair of electrons that are equally and least firmly bound to the atom. To these two types of valency electronic structure are to be ascribed not only the general and characteristic chemical properties of the elements, but also the specialized chemical properties, which differentiate the typical from the transition series of elements. For transmutation of elements *see* article under that title.

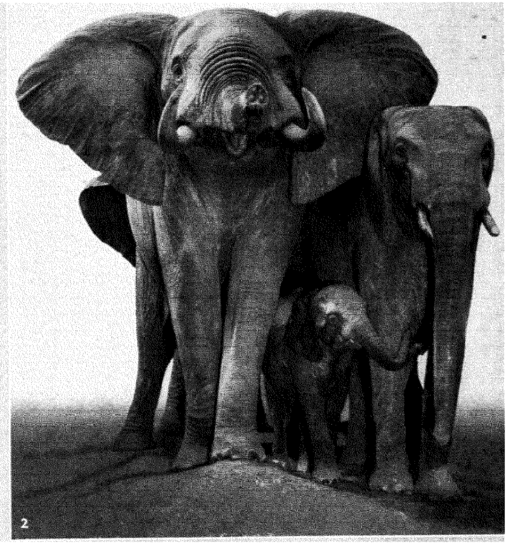
ELEMENTS, CONSCIOUS, the simplest, independently observable constituents of conscious experience. In the late 19th and early 20th centuries the conviction was widespread among psychologists that all conscious phenomena could be reduced to combinations of a limited number of simple observable constituents, termed "conscious elements." There was little agreement, however, as to the nature of these constituents. W. Wundt believed them to be of two main types,—sensations and feelings. E. B. Titchener, one of the most influential of Wundt's pupils, distinguished a third main type,—images. Chr. von Ehrenfels and other members of the school of *Gestaltqualität* insisted that consciousness involved a further class of elements, namely, form-qualities (*Gestaltqualitäten*). Yet another view was advocated by the school of "imageless thought," whose members claimed to find in consciousness certain impalpable elements which they termed knowledges (*Bewusstheiten*).

Since 1912 the attitude of psychologists toward conscious ele-



BY COURTESY OF THE AMERICAN MUSEUM OF NATURAL HISTORY

AFRICAN ELEPHANT GROUP

Front and side views of a group of elephants shot for the American Museum of Natural History, on the African expedition in 1909 under Carl Akeley (1864–1926). The group was mounted by Akeley according to the sculptural method of taxidermy originated by him. It will form the central group in the Akeley African hall in the museum

The arrangement of the group shows the bull scenting danger—feeling for scent with his trunk, ears fully extended to catch the slightest sound. The attitude of the cow indicates that she has seen the intruder and has "frozen,"—ears back, trunk pendent, prepared for either attack or retreat. The calf, conscious of the alarm, is snuggling up to its mother *for protection.* The young bull, of which only an ear and a tusk are visible, has started forward to swing around and face the danger. The big bull elephant in the front of the group, and the smaller bull behind, were shot by Carl Akeley. The cow was shot by Theodore Roosevelt and the baby by Kermit Roosevelt on the Uasin Gishu plateau, where the Roosevelt and Akeley expeditions met

Elephants which have been captured and trained for use in the logging industry in the teakwood forests of Upper Burma

ments has undergone a radical change. The works of M. Wertheimer, C. Rahn, K. Koffka and W. Koehler have shown that conscious elements such as sensations and feelings are inferential entities, not observable ones; and furthermore, that explanatory systems, which, like those of Wundt and Titchener, involve syntheses of such inferential entities, are at variance with a large number of experimental findings. There has resulted a marked tendency either to give up the concept of conscious elements entirely, or to interpret it as referring not to constituents of conscious events but to their aspects or attributes. In the latter case, conscious elements are considered not as explanatory or generative entities, but as the raw data of observation, whose variety is presumably as great as is the number of distinct predications which can be made about conscious events.

Titchener, *Lectures on the Experimental Psychology of the Thought-Processes* (1909); C. Rahn, *Psychological Monographs* (No. 67, 1913); K. Koffka, *Psychological Bulletin* (vol. xix., 1923); W. Koehler, *Psychologies of 1925* (1926). (J. G. B.-C.)

ELEMI, an oleo-resin (Manilla elemi) obtained in the Philippine Islands, probably from *Canarium commune* (nat. ord. Burseraceae), which when fresh and of good quality is a pale yellow granular substance of honey-like consistency, but which gradually hardens with age. It is soluble in alcohol and ether, and has a spicy taste with a smell like fennel. In the 17th and 18th centuries the term usually denoted an oleo-resin (American or Brazilian elemi) obtained from trees of the genus *Icica* in Brazil, and still earlier it meant oriental or African elemi, derived from *Boswellia Frereana*, which flourishes in the neighbourhood of Cape Gardafui. The word, like the older term *animi*, appears to have been derived from *enaemon* (Gr. ἔναιμον), the name of a styptic medicine said by Pliny to contain tears exuded by the olive tree of Arabia.

ELEPHANT is the name applied to the two existing species of the Proboscidea and their immediate allies. The existing elephants inhabit respectively the forest-lands of India, Burma, the Malay peninsula, Cochin China, Ceylon, Sumatra and the continent of Africa south of the Sahara.

The Asiatic elephants are distinguished by the following characteristics. They possess complex teeth, the third molar having about 24 plates. There are 5 nails on the forefoot and 4 (occasionally 5) on the hind one. There is a depression crossing the dorsal surface of the neck, and the ears are of moderate size. The trunk is smooth, not possessing the transverse ridges and grooves of the African form and at the end is a single finger-like process. The Asiatic elephants although referred to the single species *Elephas maximus*, differ a good deal amongst themselves; for instance, the Ceylon animals are generally tuskless and the elephant of Sumatra, with its slighter build and longer trunk, is equally distinct.

The Asiatic elephant lives in small herds moving about in forests in the neighbourhood of water. It has a dislike of bright sunlight and hence during the hot season keeps to the denser parts of the forest. It drinks by sucking up water into the cavity of the trunk and then discharging it directly into the mouth. Its food consists chiefly of grass, leaves, the young shoots of trees, bamboo and fruits.

The height of the male Indian elephant when full grown is usually between 8 and 10 ft. but may reach as much as 11 ft.; the calf when born has a height of about 3 feet. The adult Indian elephant is usually very sparsely provided with hair, there is the well-known tuft on the end of the tail and occasionally small patches on the forehead. The new-born elephant, on the other hand, may be covered with a continuous coat of short, grey fur. This coat is soon shed but is replaced in part by coarser and darker hair which may be comparatively abundant in individuals about 5 years old. The period of gestation is not accurately known but is about 18 months and the animal lives to about 45–60 years. One calf is usually produced at birth, but twins are known.

The African elephant (*Elephas* [*Loxodon*] *Africanus*) differs from that of Asia in its body form, the highest point lying in the middle of the back and there being no depression across the dorsal surface of the neck. Also there are transverse ridges and grooves on the trunk which possesses 2 finger-like processes at the end. The molar teeth are shallower and coarser than those of the Indian elephant, and possess only about 8 ridges in the second molars. On the worn surface the plates have a lozenge-shaped section instead of having nearly parallel sides. The ear of the African elephant is always very large, although it varies in this respect as it does in shape in different geographical races. The African elephant, although it is a woodland form, is much less averse from exposure to full sunlight than is the Indian form; it also lives in herds varying from a few to a large number of individuals. The African elephants have been separated out into about a dozen different races distinguished from one another chiefly by the form and size of the ears, but also in some cases by differences in the shape of the skull. In the Congo there is found a dwarf-race of the African elephant[1], perhaps only about half the normal height.

The Asiatic elephant has long been captured and domesticated and is used as a transport animal in India, Burma and Siam. As the animal does not breed readily in captivity, most of the tame elephants have been caught, the following method being employed. A herd is driven through a funnel-shaped palisade into a small enclosure, individuals are then cut out from the herd by tame elephants and soon learn to obey their *mahout*, even when old animals. The only other commercial use of the elephant is as a source of ivory, a trade which is rapidly leading to the extermination of the African species. The tusks of the Indian elephant may reach a length of nearly 9 ft. and a weight of 100 lb., whilst the African elephant tusks may be 10 ft. in length, with a weight of 220 pounds. The female Indian elephant usually has small tusks, if any at all, but in the African species the female tusks are always large, as they are extensively used by the animal in feeding. African elephants are not now tamed, although they are actually as tractable as the Indian form, and were tamed and used in warfare by the Carthaginians and Romans.

Fossil elephants very similar in structure to those now living existed during Pleistocene times throughout Europe, Africa, Asia and North America. They belong to several species, of which the best known is the mammoth (*q.v.*). Amongst the others the most interesting are the dwarf forms whose remains are found in cave deposits in the islands of the Mediterranean, Cyprus, Malta and Crete. The smallest of these is a Cretan form, which in the adult stood about 3 ft. high. The whole group appear to be local varieties of *Elephas antiquus*, a straight-tusked elephant found essentially over the whole of Europe, India and Africa; it includes also gigantic individuals such as the one now mounted in the British Museum which was found in Kent, and has a height of about 14 feet, probably the greatest height to which any elephant has attained. (*See* also MASTODON.)

(D. M. S. W.)

ELEPHANTA, a small island between Bombay and the mainland of India, situated about 6 m. from Bombay (native *Gharapuri*). It is nearly 5 m. in circumference, and the few inhabitants it contains are employed in the cultivation of rice, and in rearing sheep and poultry for the Bombay market. The island, till within recent times, was almost entirely overgrown with wood; it contains several springs of good water. There are also important quarries of building stone. But it owes its chief celebrity to the famous Temple Caves, standing on a plateau and approached by a long flight of steps. The entrance is nearly 60 ft. wide and 18 high, supported by pillars cut out of the rock; the sides are sculptured into numerous compartments, containing representations of the Hindu deities, but many of the figures have been defaced. In the centre of the excavations is a remarkable *Trimurti* or bust, thought to be a triform representation of Siva. The heads are from 4 to 5 ft. in length, and are well cut. The head-dresses are curiously ornamented; and one of the figures holds in its hand a cobra, while on the cap are, amongst other symbols, a human skull and an infant. On each side of the Trimurti is a pilaster,

[1]The height of a large bull African elephant may reach eleven ft. and the weight 6–8 tons.

the front of which is filled up by a human figure leaning on a dwarf, both much defaced. There is a large hollowed compartment covered with figures, the largest of which is 16 ft. high, representing the double figure of Siva and Parvati, named Viraj, half male and half female. On the right is Brahma, four-faced, on a lotus—one of the very few representations of this god which now exist in India; and on the left is Vishnu. On the other side of the Trimurti is another compartment with various figures of Siva and Parvati, the most remarkable of which is Siva in his vindictive character, eight-handed, with a collet of skulls round his neck. On the right of the entrance to the cave is a square apartment, supported by eight colossal figures, containing a gigantic symbol of Mahadeva or Siva cut out of the rock. In a ravine connected with the great cave are two other caves, also containing sculptures, much defaced, and in another hill is a fourth cave. This interesting retreat of Hindu religious art is said to have been dedicated to Siva, but it contains numerous representations of other Hindu deities. It forms a wonderful monument of antiquity, and must have been a work of incredible labour. The cave is thought to have been excavated about the 10th century of the Christian era, if not earlier. The island is much frequented by the British residents of Bombay and few visitors to the city leave without making a trip to Elephanta.

ELEPHANT-HEAD (*Pedicularis groenlandica*), a North American plant of the figwort family (Scrophulariaceae), native to wet soil from Greenland to Alaska and southward on mountains to New Mexico and California. It is a smooth, erect perennial, about a foot high, bearing pinnately divided leaves and a dense cluster (spike), 2 in. to 6 in. long, of crimson flowers, irregular in shape, with the upper lip produced into a long beak, at first bent downward but soon curving forward and upward, the whole strikingly suggestive of an elephant's head. The plant, which blooms in midsummer, is an interesting floral feature of alpine meadows in the national parks of the western United States and Canada. A closely related species, *P. attollens*, of high mountains in California, with white or pinkish flowers marked with purple, but lacking the long beak, is known as elephant-snouts.

ELEPHANTIASIS, ĕl-ĕf-ănt-ī′ăs-ĭs (*Barbadoes leg; Boucnemia*), a disease dependent on lymphatic obstruction and characterized by hypertrophy of the skin and subcutaneous tissue. Two forms are known: (1) elephantiasis arabum, due to filariasis (*q.v.*); (2) the non-filarial form due to lymphatic obstruction from any other cause, as erysipelas, the deposit of tuberculous or cancerous material in the lymphatic glands, phlegmasia dolens (white leg), long-continued eczema, etc. The enlargement is limited to a particular part of the body, generally one of the lower limbs, rarely both, or the scrotum, one of the labia, or the mammary gland; far more rarely the face. An attack is usually ushered in by fever (elephantoid fever), the part attacked becoming rapidly swollen and the skin tense and red as in erysipelas. The subcutaneous tissues become firm, infiltrated, and hard, pitting only on considerable pressure. The skin is roughened with a network of dilated lymphatics and bullae may form, discharging a chyle-like fluid when broken (lymphorrhoea). In a later stage still the skin may be coarse and wart-like, and there is a great tendency for varicose ulcers to form. At the end of a variable time enlargement ceases to take place and the disease becomes quiescent, but recrudescences occur at irregular intervals, always ushered in by elephantoid fever. At the end of some years the attacks of fever cease and the affected part remains permanently swollen. The only difference in the history of the two forms of the disease lies in the fact that the non-filarial form progresses steadily, until either the underlying condition is cured or death occurs. The elephantiasis due to filaria is due to lodgment of the parasites in the lymphatics and lymph spaces.

Treatment is unsatisfactory. Occasionally the dilated lymph trunks can be found and an operation performed to implant them in some vein (lymphangeioplasty). And in some few other cases artificial lymphatics have been made by introducing sterilized silk thread in the subcutaneous tissues of the affected part and prolonging it into the normal tissues. This operation has been applied to the elephantoid arms dependent on a late stage of cancerous breast. Elevation of the limb and elastic pressure should always be tried, but often amputation has to be resorted to in the end. The disease is totally different from the so-called elephantiasis graecorum or true leprosy, for which *see* Leprosy.

ELEPHANT MOUND. A prehistoric earthwork in the Upper Mississippi and Lakes region—where effigy earthworks are common. It is near Wyalusing, Grant county, Wisconsin, and received its name from its massive form and a conjectured prolongation of the nose, supposed to be a part of the original mound when first brought to notice in 1872. The immediate situation is a long rectangular depression, the level of which is only a few feet above the Mississippi at high water. The highest point of the mound (4 ft.) was the hip of the effigy, the length was 140 ft., and the width across the body and to the lower end of the hind leg, 72 feet. When surveyed in 1884 no indication of an elephant-like proboscis was found, and it has long been believed that the effigy was intended to represent a bear.

ELEPHANT'S-FOOT, the popular name for the plant *Testudinaria Elephantipes,* a native of the Cape of Good Hope. It takes its name from the large tuberous stem, which grows very slowly but may reach a size of more than 3yd. in circumference with a height of nearly 3ft. above ground. It is rich in starch, whence the name Hottentot bread, and is covered outside with thick, hard, corky plates. It develops slender, leafy, climbing shoots which die down each season. It belongs to the monocotyledonous family Dioscoreaceae (*q.v.*), which includes the yam and the black bryony, *Tamus communis,* the latter found in Britain.

ELETS, a town in the Orel province of the Russian S.F.S.R., situated on the Sosna R., a tributary of the Don, in lat. 52° 37′ N., long. 38° 10′ E. Its population, 42,492 in 1926, has increased rapidly owing to its favourable situation as a junction for five railway lines. It has an electric generating plant, and its industrial undertakings include iron founding, lime-burning, leather preparation and tobacco works. It is an important grain and cattle centre: the first grain elevator in Russia was erected here in 1887. The cathedral and two monasteries contain historic relics. Elets is first mentioned in 1147, when it was a fort of Ryazan. The Turkish Polovtsi or Kumans attacked it in the 12th century, and the Mongols destroyed it during their first invasion (1239) and again in 1305. The Tatars plundered it in 1415 and 1450; and it seems to have been completely abandoned in the latter half of the 15th century. Its development dates from the second half of the 17th century, when it became a centre for trade with south Russia.

ELEUSIS, an ancient city of Greece about 14 m. W. of Athens, on a rocky ridge close to the shore of the bay of the same name opposite the island of Salamis. Its fame is due to its Mysteries (*see* Mystery). Tradition carries back its origin to the highest antiquity. In earlier history it seems to have been independent of Athens. Of its small territory the plain of Thria was fertile, though swept by blighting winds. To the west was the Rharian Plain, where Demeter is said to have sown the first seeds of corn; and the field called Orgas, planted with trees consecrated to Demeter and Persephone. The sacred buildings were destroyed by Alaric in A.D. 396. The present village (Lefsina or Lepsina, officially 'Ελευσίς) is Albanian.

The Site.—The Greek Archaeological Society has laid bare since 1882 the whole of the sacred precinct, traced its extensions at various periods and revealed successive stages in the structure of the Telesterion, or Hall of Initiation.

In front of the main entrance is a paved area, with the temple of Artemis Propylaea of Roman date; on each side of the Great Propylaea stood a Roman triumphal arch. Just below the steps of the Propylaea, on the left, a curb surrounding an early well marks almost certainly the καλλίχορον φρέαρ mentioned by Pausanias. The Great Propylaea is of Roman imperial date, set in a wall of 6th-century work, repaired in later times, which encloses an outer court, of irregular shape. The Small Propylaea, not set exactly opposite to the Great Propylaea, was built by Appius Claudius Pulcher, the contemporary of Cicero. It is in a later wall which, like two earlier ones of the 6th and 5th centuries,

bounded the inner precinct. Thence a paved road of Roman date leads to one of the doors of the Telesterion. Above the Small Propylaea, partly set beneath the overhanging rock, is the precinct of Pluto; it has a curious natural cleft approached by rock-cut steps. Here was found the famous head, now in Athens, usually called Eubouleus. Farther on a rock-cut platform approached by broad steps probably served for spectators. Beyond this, on higher ground, close to the side of the Telesterion, stood a small temple, unidentified.

The Telesterion (Hall of Initiation) was a large covered building, about 170 ft. square, surrounded on all sides by steps partly cut in the solid rock, which served as seats for the mystae, while the sacred rites took place on the floor. There were two doors on each side of the hall, except the north-west, where it is cut out of the solid rock, and a rock terrace at a higher level adjoins it. The roof was carried by rows of columns, more than once renewed.

The architectural history of the hall has been traced with the help of various foundations. The earliest building was small, rectangular, of polygonal masonry, quarried on the spot. This was succeeded by a square hall, almost of the same plan as the later Telesterion, but about a quarter of the size; its eastern corner coincides with that of the later building, and it had a portico in front and internal columns. This has been assigned to the time of Peisistratus; was destroyed by the Persians and partly rebuilt soon after; only to be replaced by the much larger Periclean hall designed by Ictinus, with projecting foundations for a portico or for angle buttresses, to resist the thrust of the roof. This hall is faced with a portico which was designed by the architect Philo (*c.* 300 B.C.); the marble pavement is a most conspicuous feature.

The Telesterion took up the greater part of the sacred precinct, and the massive walls and fortress towers of the time of Pericles are quite close to it; later the precinct was extended to the south, and at its end was erected a building, probably the Bouleuterion, rebuilt in Roman times. The precinct was full of altars, dedications and inscriptions. Its subterranean passages are nothing but cisterns or watercourses.

The excavations of Eleusis, and the antiquities found in them, have been published from time to time by the Greek Archaeological Society. *See* also D. Philios, *Éleusis, ses mystères, ses ruines, et son musée.* Inscriptions in *Bulletin de correspondance hellénique.*

ELEUTHERIUS, pope from *c.* 175 to 189. Allusions to him are found in the letters of the martyrs of Lyons, cited by Eusebius, and in other documents of the time. The *Liber Pontificalis,* at the beginning of the 6th century, says that he had relations with a British king, Lucius, who was desirous of being converted to Christianity. This tradition—Roman, not British—is an enigma to critics, and, apparently, has no historical foundation.

ELEUTHEROPOLIS, an ancient city of Palestine, 25 m. from Jerusalem, on the road to Gaza, mod. Beit Jibrin (Gabriel); pop. 1,000.

History.—Marēshah was the name of the settlement in Old Testament times, now Khirbet Mar'ash, about 1 m. S.W. of Beit Jibrin beside Tell Sandahanna (St. John), on which are the ruins of an early church of that name. Marēshah was fortified by Rehoboam, sacked by Judas Maccabeus (163 B.C.), and taken by John Hyrcanus (110 B.C.). Pompey restored it to independence (63 B.C.), and in 40 B.C. it was completely destroyed by the Parthians. The Romans rebuilt it as a fortress on the modern site with the name Baitogabra. Septimius Severus showed it favour and gave it the name Eleutheropolis ("free city") (A.D. 200). It boasted an era of its own, with the year 199 as zero year. In the course of the 9th century the old name reappeared as Beit Jibrin. On this site, the name of which they corrupted to Gibelin, the crusaders built a castle (1134), which fell into the hands of Saladin (1187), was retaken by Richard Lionheart (1191), and destroyed by Beibars (1264). During the World War the Turkish troops, who had entrenched themselves in the caves in its neighbourhood, were surprised and dislodged by Australian cavalry, Nov. 11, 1917.

Archaeology.—The hills in the neighbourhood of Tell Sandahanna are honeycombed with caves, some of great dimensions, which have been cut out of the soft rock. They are thought to be of early date. They seem to have been used in different ages for a variety of purposes—dwellings, tombs (one with about 2,000 columbaria), chapels, cisterns, etc. Some of the caves were decorated in the Roman period with paintings, which are now carefully protected. More recently (1922) at Tell Sandahanna, the site of a Roman villa of the 2nd century A.D., on which had been superposed a church, has been excavated. In one of its chapels there has been discovered a most wonderful mosaic, the finest example of its kind yet found in Palestine.

See H. Thiersch and J. P. Peters, *Painted Tombs in the Necropolis of Marissa* (Mareshah, 1905); F. M. Abel, "Découvertes récentes à Beit-Djebrīn," *Revue Biblique* (1924).

ELEUTHEROPOULOS, ABROTELES (1873-), German philosopher of Greek descent, was born on May 24, 1873, in Constantinople. He studied at Leipzig, and since 1896 has been *a privatdozent* at Zürich. He desired to put philosophy on a scientific basis and investigated its relation to sociology and economics. Besides his chief work, *Wirtschaft und Philosophie* (1898; 3rd ed., 1915), he has written *Einführung in eine wissenschaftliche Philosophie* (1900); *Sociologie* (1904; 2nd ed., 1908); *Rechtsphilosophie, Sociologie und Politik* (1908); *Seelenleben* (1911) and *Philosophie, allgemeine Weltanschauung* (1911).

ELEUTS. The western Mongols, certain of whom are called Kalmucks by their neighbours, although this term has been very loosely used, were called Urat by the Manchus, U-lat by the Chinese, and in western languages, through the Russian this term became Eleut. Some of them, notably the Torgots (Torgod) have migrated as far west as the Volga, whence they returned, and to-day their descendants are settled in the Ili district. Their culture and relationships are discussed in MONGOLIA: *Ethnology,* of which group they form an important part.

ELEVATOR, GRAIN: *see* GRANARIES.

ELEVATORS are designed to transfer people or materials from one level to another in a vertical direction with safety. Complete installations comprise the elevator machine with its motive power and controller, platform and enclosure in a hatchway operating on guides and with the necessary connecting cables, sheaves and other accessories. There are many types of elevators in use, operated by hand, steam, belt, hydraulic or electric power. Those installed recently (1928) have been almost exclusively of the electric type. There is a wide variation in their construction, depending upon the motive power, type of building served and the character of service to be performed.

The modern elevator dates from a platform hoist made by Henry Waterman in New York, in 1850, this being a very crude affair, operating between two floors. At about the same time George H. Fox and Company of Boston were building the same type of elevator and sending it to other parts of the country. In 1852 Elisha Graves Otis began the manufacture of elevators at Yonkers, N.Y., and in 1854 invented the first safety device to prevent the falling of the car platform in case the ropes should break.

Early Types.—The first passenger elevator was installed by Otis in 1857 in New York. The distinction of being the first passenger elevator has been claimed for an elevator installed by Otis Tufts, of Boston, in New York, which was known as the "vertical railway," but this was not installed until 1859. This "vertical railway" had as its principal feature an immense vertical screw, by means of which the car platform was raised and lowered. It was not, however, successful and only two of them were installed. The oscillating cylinder steam engine and the stationary cylinder steam engine which replaced it, were both invented by the Otis organization and remained in use until superseded by the hydraulic type. In 1878, Charles R. Otis invented the safety governor. The first passenger elevator in an office building was of the steam-driven type and was installed in New York in 1869. About this time steam driven belt machines were standard for factory elevators.

Hydraulic Elevators.—Early in the '70s, hydraulic machines were introduced and had many advantages over the steam machines, principally that of increased speed. This development of the hydraulic elevator began with the direct acting plunger

elevator which, however, was soon superseded for all except low rises, by the vertical hydraulic elevator, invented by Cyrus W. Baldwin. This type of elevator was rapidly developed for increased rises of elevators and improved forms of control. The early machines were operated by a hand rope in the car, but as speeds increased so that this was impossible, there was invented the differential valve and the pilot valve, operated by a lever device in the car. In meeting demands for higher buildings and consequently greater speeds, water pressures were rapidly increased which, together with further developments in the controlling system of the car, soon made available car speeds of 600 ft. per minute, which at that time was considered marvellous.

Electric Elevators.—In 1887 William Baxter, Jr., designed and installed an electric elevator in Baltimore, which was not successful. In 1889 the first successful electric elevator installation was made by Otis Brothers and Company in New York. This elevator remained in service about 35 years. The early electric elevators were of the drum type in which the hoisting cables were wound on the drum which was driven from an electric motor through a worm and gear reduction. These early machines were controlled by hand rope which, however, soon gave way to a lever device somewhat similar to that used with hydraulic elevators. In a few years this was superseded by what was known as the "magnet control," by means of which the car was stopped and started from a switch in the car itself, which operated electro-magnets on a control board.

Shortly after the development of car switch control for electric elevators, there was placed on the market the automatic push button type of control. This type was intended primarily for private residences and apartments and was operated by means of buttons in the car corresponding to the floors served and by buttons at the entrances on each floor. No operator was required and the passenger operated the car by pressing the buttons. This type was limited to slow speeds on account of the difficulty in making level landings under all conditions of loading, and they could only be used where the service was light as only one passenger at a time could be served. Combination door locks and switches were provided to prevent the opening of the hatchway doors until the car was stopped at the landing and to prevent the operation of the elevator if any of the hatchway doors were open.

It was only a few years after its invention that the electric elevator began to take the place of the hydraulic elevator in all except the highest buildings. This was due to its higher efficiency, its easier handling and because much less space was required for machinery. The early electric machines were all of the direct current type and it was not until April 1898, that the Otis organization installed the first alternating current electric elevator, which was mechanically controlled, as electro-magnets were not yet adapted for that character of current.

In 1899 the plunger type of elevator was developed for high rise, high speeds. The claim of safety put forth was that the elevator could not fall. There were, however, many inherent disadvantages and this type of elevator for high rises had a very brief period of popularity. The electric elevator of the worm geared type, as then developed, had two disadvantages which prevented its ready adoption for the then highest type of building. Elevator travel was limited because the hoisting ropes were wound on the drum, the face of which necessarily projected in the hatchway, and the face of the drum was limited by the space available in the width of the hatch. The result was that the vertical hydraulic elevators continued in use for high speed service.

1:1 Gearless Traction Elevator.—In 1904 the Otis Elevator Company installed in Chicago, the first gearless traction electric elevator apparatus, which was of the direct drive type, known as the 1:1 elevator. This elevator machine consisted of a slow speed motor with the driving sheave mounted directly on the armature shaft and with an electric brake on the same shaft. The hoisting ropes attached to the car ran directly to the driving sheave on the machine and around that and a secondary sheave, and directly to the counterweight. This direct drive, without any intermediate gear reduction, and with the slow speed motor, permitted car speeds of 550 to 600 feet. This type of machine was placed over the hatchway and so saved a great deal of valuable space in the basement. They developed very high efficiency and were easily operated at high speed. This machine was perfected rapidly and within a few years had come into general use for all high speed service.

Where it is desired to use a gearless traction machine for very heavy duties at slower speeds, it is possible to utilize the gearless machine with rope gearing of 2:1 by means of sheaves on the top of the counterweight and on the steel frame of the elevator car. By 1916 an improvement on the worm gear drum type machine was made which consisted of the use of a driving sheave instead of a drum and which became known as the single wrap traction geared elevator. This improvement provided the geared type of elevator with greater safety, as it gave it the inherent advantage of the traction type of drive in that if the car or counterweight should bottom in the hatchway the other member would not be drawn into the overhead work, as had happened with the drum type machine.

MODERN IMPROVEMENTS

Micro-drive or Self-levelling Elevator.—With this type, the elevator platform is automatically levelled exactly with the floor landing at each stop, irrespective of the operator. This eliminates "inching" at the floors, with consequent saving of time. It also saves power consumption and wear on the machinery.

Automatic Operation.—In 1924 an important advance was made in elevator operation by the invention of the Otis automatic signal control. The entire operation is automatic and controlled by the pressing of buttons in the car by an attendant, or on the floors of the building by the waiting passengers. Upon being given the signal to start, the attendant releases the doors, which close automatically. The elevator then starts automatically and runs to the first floor for which a button has been pressed, where the car stops automatically and the doors open automatically. After the passenger has alighted the attendant releases the doors and the cycle of operation is repeated at each floor for which a button has been pressed. In the meantime waiting passengers press buttons at the floors, indicating the direction in which they wish to travel. Each call is automatically registered on the first elevator travelling in the proper direction, which then automatically stops at that floor, without even the foreknowledge of the attendant. This type of control is supplied with micro-drive, which enables these elevators to be operated at speeds up to 900 or 1,000 ft. per minute, and as much higher as may be required by buildings of the future. These high speeds are made possible by the automatic levelling, as cars travelling at such speed could not be satisfactorily handled by manual operation of an operator, with car switch control.

A form of control which has become very popular in the United States in recent years and which is known by various names such as unit multi-voltage, variable voltage, etc., was patented many years ago by Ward Leonard and has been used extensively outside of the elevator industry wherever considerable variation of speed and smooth retardation and acceleration were desired. In the elevator industry it consists of an individual generator driven by direct or alternating motor-supplying current to the elevator motor. A further development of the automatic signal control is the collective automatic control and the department store control. The collective automatic control is an outgrowth of the ordinary automatic push button elevator used for private residences and small apartment houses as previously described. With the collective type of control, combined with micro-drive, speeds of 450 ft. per minute may be attained with perfect stopping, and the control is so arranged that the elevator will stop at each floor for which a button has been pressed in the direction in which the car is travelling. These improvements make it possible to use this type of elevator without an operator in larger apartments and small hotels.

The department store type of control is designed for buildings of that character, or other service where stops are usually made at each floor in both directions. With this system there are no floor buttons required, nor is the attendant required to press any buttons in the car. Upon the releasing of the doors at the first floor, which close automatically, the car then starts automatically and runs to the next floor, where it stops automatically and the doors are

opened automatically, this cycle being repeated at each floor. It is possible, however, by the movement of a switch in the car to have the elevator travel past any floors without stopping. There are variations of both collective control and department store control to suit individual requirements of certain buildings.

A form of automatic operation for freight elevators in large groups is known as the operatorless control, used with a number of elevators in one or more banks. With this system there is one central operator for each group who receives by telephone all calls from any floor where an elevator is required. He has before him an indicator board which shows him the position of all elevators at all times and whether they are in use or not. By means of buttons on his desk, which automatically control all of the elevators, he then dispatches the nearest available elevator to the floor where it is needed. This effects a great saving in time and eliminates the possibility of waiting for an elevator that is in use.

Safety Devices.—The first essential of an elevator installation is the inclusion of all necessary safety devices to accomplish this purpose and prevent accident or injury. The early builders, with very crude machines, did not require any devices other than that of one over the platform to prevent its falling in case the ropes should break. As the machines developed in character, capacities and speed, various other devices were put into operation to take care of increased hazards until at the present time the electric elevator of the reputable manufacturers has a number of safety devices which cover practically every condition which might occur.

In addition to the safety device under the car connected with the automatic speed governor, there is also, on high speed installations, a switch on the governor which cuts off current to the motor and applies the brake if the car should attain excessive speed. Automatic stopping and final limit switches are provided to slow down and stop the car at the terminal landings in case the operator should fail to throw the car switch, or in case an automatically controlled machine should run beyond its normal stopping point. Buffers are provided in the pit to bring the car to a gradual stop if other safety devices should fail. On high speed installations, these long stroke oil buffers are so arranged that if the car lands upon them they are gradually compressed and checked by oil circulating through graduated openings. Featured in the traction type of plant, in which, where neither the car nor the counter-weight can be pulled into the overhead work if the other should be checked in its descent, buffers mean that another possibility of accident is eliminated.

All automatic types of elevators used without a regular operator have the interlocking door locks and contacts as heretofore described. In many American cities the regulations now require that all passenger elevators shall have a gate or door on the platform, with a switch so connected that the car cannot be operated while this gate is open. This prevents any possibility of passengers in the car coming in contact with the side of the hatchway while the elevator is running.

Signals.—The early annunciator in the car to notify the operator of calls has given place on the high speed elevators to flash light signal systems of several types. When service is not continuous the flash light annunciator is used; this being automatically reset when the call is answered. In continuous service, as in office buildings where the elevators are kept running continuously, the signal system on car switch controlled elevators is such that the pressing of a button by a waiting passenger on any floor signals the first car in the desired direction by flashing a light when the car is approximately two floors away, thus notifying the operator of the call. This light is extinguished when the car passes the floor. There is also provided with this system an "up" and "down" signal lantern in front of each elevator at each floor to notify the passenger as to which elevator will service his call. On signal control elevators the pressing of a button on any floor registers the call on the elevator controllers. Signal lanterns are provided on each floor.

Influence of Elevators on Buildings.—Before the advent of the elevator it was not feasible to construct buildings more than a few storeys in height. The early elevators permitted of a few additional storeys. As the speed and reliability of elevators increased this improvement was reflected in the taller buildings which sprang up in the larger cities. With the coming of the steel skeleton building structure builders saw the possibilities of increased returns from their property, especially in the more congested districts where land values are high, and turned to the elevator as the means of making it possible to rent such buildings advantageously.

The development and application of gearless electric elevators which removed the height limitation of building as far as the elevator is concerned, was immediately reflected in the 41 storey Singer building in New York. Since 1924, coincident with the development of the still higher speeds of the signal control elevator, there has been a tremendous increase in the number of high buildings erected in the larger cities throughout the United States. The present maximum car speed of 900 ft. per minute has already been exceeded in estimates for still higher speeds in buildings which might require it. It would thus appear that no matter to what extent the builders may aspire in the height of their buildings, elevator manufacturers will be able to meet their requirements.

In office buildings the character of elevator service is frequently the most important feature in the success of the building. Elevators in a building are divided into those for local service, approximately from the 1st to the 10th floor; then express elevators serving the 10th to 20th floors; another group making no stops to the 20th, and serving from there to the 30th and so on. In this way the offices on the upper floors become practically as easy of access as those on the lower floors and are frequently more desirable on account of the better light and ventilation and freedom from street dust and noise. (J. H. Van A.)

ELF, a diminutive supernatural being of Teutonic mythology, usually mischievous, causing diseases and evil dreams, stealing children and substituting changelings; differs from the Romanic, less sinister fairy. (O.E. *aelf; cf.* Ger. *Alp*, nightmare.) The prehistoric flint implements, in England known as "elf-bolts" or "elf-arrows," were looked on as the weapons of the elves, with which they injured cattle. A tangle in the hair was called an "elf-lock."

ELGAR, SIR EDWARD (1857–), English composer, was born at Worcester on June 2, 1857. His father was organist of the Roman Catholic church of St. George in that city, and had connections with the Glee Club and the Three Choirs Festival. He was also a violinist, and both he and his son played in the Festival orchestra. The boy also played the organ and occasionally the bassoon, and sometimes led the Glee Club band. He had no regular musical education. In 1879 he became bandmaster at the county lunatic asylum; in 1882 he was engaged as conductor of the Worcester amateur orchestral society; and in 1885 he succeeded his father as organist at St. George's. In 1889 he married Caroline Alice, daughter of Maj.-Gen. Sir Henry Gee Roberts and in the same year he moved to London; but finding no encouragement there he retired to Malvern in 1891, and in 1894 settled in Hereford. From 1905 to 1908 he was professor of music at Birmingham university.

To the public generally Elgar's name was little known until the production of his oratorio, *The Dream of Gerontius.* This work, first performed at the Birmingham Festival in 1900 under Richter, did not at first receive the recognition which it merited. Portions of it, such as the death scene and the "Angel" music, made an instant impression, but the whole was felt to be disappointing. A section of the audience objected to its "Catholicism," though to others, who appreciated the spiritual affinity existing between the music and Newman's poem, this was the element that was most precious. It was not until the performance of the oratorio at the Lower Rhine Festival at Düsseldorf on May 19, 1902, under Julius Buths, when it elicited from Richard Strauss a generous tribute which attracted universal attention, that its position was assured. Elgar's next great work was *The Apostles,* forming the first part of a trilogy, which was produced at the Birmingham Festival of 1903 and performed at the Lower Rhine Festival in Cologne in 1904. Its reception in both cases was disappointing. Made of sterner stuff than *Gerontius,* it was not calculated to appeal to those who had taken that work to their

hearts. The harshness of some of the progressions was displeasing to English festival audiences who had been brought up on Mendelssohn and Spohr, but subsequent performances brought a revulsion in its favour. Elgar's growing popularity led to the organization, in March 1904, of an Elgar festival of three days at Covent Garden, London, at which *Gerontius, The Apostles* and the concert overture, *In the South,* were performed. The last is one of the composer's finest works, remarkable for the broad lines of its melody and its warm colouring, and interesting as a foretaste of the great symphonic writing that was to come. In 1906 *The Kingdom* (op. 51) (part II. of the trilogy), was produced at the Birmingham Festival.

The appearance of the first symphony (in A flat, op. 55), first played in Manchester on Dec. 3, 1908, marked the opening of a new phase. Where the massive choral works had failed to convince and impose, the symphony now succeeded. Its breadth, its beauty and its sincerity left no doubt, from the first time of hearing, of its importance. Its reception abroad was almost as enthusiastic, and in the result it was hardly going too far to say that English music had been raised to a higher position in the estimation of Europe than any which it had occupied since the death of Purcell. After the symphony came the violin concerto (op. 61), the second symphony (op. 63) and the symphonic study for orchestra, *Falstaff* (op. 68). The concerto was first played by Kreisler at a Philharmonic concert in London in 1910 and, like the first symphony, attained immediate popularity.

The World War inspired Elgar to write some patriotic pieces, one of which, *Carillon* (op. 75), written to a poem by Émile Cammaerts, had innumerable performances. These works were followed by *Polonia*, a symphonic prelude, and *Le Drapeau Belge* (op. 79). After the war Elgar turned his attention to chamber music, producing in a single year (1919) the violin and piano sonata (op. 82); the string quintet (op. 83); the piano quintet (op. 84) and the violoncello concerto, all works of the finest quality. Since the death of his wife in 1920, he has produced little beyond two brilliant transcriptions for orchestra of a fugue by Bach and an overture by Handel, but it is believed that there are other works still to come.

Many of Elgar's earlier compositions were revived when his fame became established and have become permanent favourites with the British public. Among these are the *Pomp and Circumstance* marches (op. 39), the first of which contains as its *trio* the stirring melody now sung to the words of "Land of Hope and Glory"; the song-cycle, *Sea-Pictures,* first sung at Norwich by Dame Clara Butt in 1899; the "Enigma" *Variations for orchestra on an original theme;* the overture *Cockaigne* and the two orchestral suites *The Wand of Youth,* written on material dating from the composer's childhood. Among these, the Variations stand easily first and have indeed long since taken their place, alike at home and abroad, among the most important of all Elgar's instrumental works; the *Sea-Pictures,* though on a lower level, rank none the less among the best of Elgar's songs, while *Cockaigne* has also proved very popular, not least on the continent, where it is regarded as a typical picture in tones of London's busy life. Still earlier works include the popular *Salut d'amour* for violin and piano; *Sursum corda* for brass, strings and organ; a concert overture *Froissart; Spanish Serenade* for chorus and orch.; *The Black Knight,* cantata; *The Light of Life,* oratorio; and *Scenes from the Saga of King Olaf* for soli, choir and orch.

Elgar received his knighthood in 1902, at the time of King Edward VII.'s coronation, for which he wrote the official Ode. In 1900 he received the degree of Mus. D. from Cambridge university, and in 1905 from Oxford and from Yale. The Order of Merit was conferred on him in 1911, while he succeeded Sir Walter Parratt as Master of the King's Musicke in 1924.

For further information concerning the composer, *see* an excellent and comprehensive article in *Grove's Dictionary* (3rd ed.); R. J. Buckley, *Sir Edward Elgar* (1904); Ernest Newman, *Elgar* (1906); J. F. Porte, *Sir Edward Elgar* (1921).

ELGIN, a royal and municipal burgh, and county town of Moray, Scotland, situated on the Lossie, 5 m. S. of Lossiemouth its port, on the Moray Firth, and 37 m. N.E. of Inverness, with stations on the L.N.E.R. and L.M.S.R. Pop. (1921) 7,776. It was created a royal burgh by Alexander I., and received its charter from Alexander II. in 1234. Edward I. stayed at the castle in 1296 and 1303, and to blot out the memory of his visit the building was destroyed immediately after national independence had been reasserted. The hill on which it stood was renamed the Ladyhill. In 1452 half of the town was burnt by the earl of Huntly. Montrose plundered it twice in 1645. In 1746 Prince Charles Edward spent a few days in Thunderton House. For 50 years after this date the place remained a sleepy cathedral city, but with the approach of the 19th century much that was picturesque disappeared, though its prosperity increased. The cathedral of Moray was founded in 1224, when the church of the Holy Trinity was converted to this use. It was partially burned in 1270 and almost destroyed in 1390 by Alexander Stewart, the Wolf of Badenoch, natural son of Robert II. In 1402 Alexander, lord of the Isles, set fire to the town, but spared the cathedral for a consideration, in memory of which mercy the Little Cross (so named to distinguish it from the Muckle or Market Cross, restored in 1888) was erected. After these outrages it was practically rebuilt on a scale that made it the finest church in the north. Its design was that of a Jerusalem cross, with two flanking towers at the east end, two at the west end, and one in the centre, at the intersection of the roofs of the nave and transepts. The central steeple fell in 1506, but was rebuilt, the new tower with its spire reaching a height of 198 ft. By 1538 the building was complete in every part. Though the Reformation left it unscathed, it suffered wanton violence from time to time. The central tower again collapsed in 1711, after which the building was allowed to go to ruin. Its stones were carted away, and the churchyard, overgrown with weeds, became a dumping-ground for rubbish. It lay thus neglected until 1824, when John Shanks, a "drouthy" cobbler, was appointed keeper, and conceived the notion of restoring the place to order. When he died in 1841 he had cleared away all the rubbish, disclosed the original plan, and collected a quantity of fragments. A tablet, let into the wall, contains an epitaph by Lord Cockburn, recording Shank's services to the cathedral which was later entrusted to the custody of H.M. Office of Works. The chapter-house, to the north-east of the main structure, suffered least of all the buildings, and contains a 'Prentice pillar, of which a story is told similar to that of the ornate column in Roslin chapel. General Andrew Anderson (1746–1822) endowed the Elgin Institution (commonly known as the Anderson Institution) for the education of youth and the support of old age. Within the cathedral precincts stood the bishop's palace (now in ruins), the houses of the dean and archdeacon (now North and South colleges), and the manses of the canons. Other ecclesiastical buildings were the monasteries of Blackfriars (1230) and Greyfriars (1410) and the preceptory of Maisondieu (1240). They also fell into decay, but the third marquess of Bute restored the Greyfriars' chapel in part. Gray's hospital, at the west end of High Street, was endowed by Dr. Alexander Gray (1751–1808). There is a museum of antiquities and natural history and a Victoria school of science and art. In 1903 G. A. Cooper presented his native town with a public park laid out for sports and skating. Grant Lodge, an old mansion of the Grant family, occupying the south-west corner of the park, was converted into the public library, museum and art gallery. From the top of Ladyhill the view commands the links of the Lossie and the surrounding country, and a recreation ground is laid out on Lossie Green.

The industries include distilling, nursery gardening, tanning, and there are saw and flour mills, iron-foundries and manufactures of woollens, and stone quarrying. There are weekly corn and cattle markets. The town has a council with provost and bailies.

Two miles and a half south by west of Elgin stands the church of Birnie, with the exception of the church at Mortlach in Banffshire probably the oldest place of public worship in Scotland still in use. Its date is not later than 1150 and, with its predecessor, it was the cathedral of Moray during the rule of the first four bishops; the fourth bishop, Simon de Toeny, an Englishman, was buried in its precincts in 1184. In the church is preserved an old Celtic altar-bell of hammered iron, known as the "Ronnell bell."

Six miles south-west of Elgin, in a secluded valley, lies Pluscarden Priory, a Cistercian house founded by Alexander II. in 1230. The ruins consist of tower, choir, chapter-house, refectory and other apartments. The *Liber Pluscardensis,* a valuable authority on early Scottish history down to the death of James I., was compiled in the priory by Maurice Buchanan in 1461.

ELGIN, a city of Kane county, Ill., U.S.A., on the Fox river, 36m. N.W. of Chicago. It is on Federal highway 20, and is served by the Chicago and North Western, the Chicago, Aurora and Elgin, and the Chicago, Milwaukee, St. Paul and Pacific railways. The population was 33,384 in 1927, when a special census was taken under the supervision of the census bureau. Elgin is in a fine dairying region, and has a large trade in butter, cheese and agricultural produce. Water power is abundant, and there are important manufactures (notably watches and watch-cases, condensed milk, butter tubs and meat products), with an aggregate output in 1925 valued at $30,064,803. The Elgin National Watch company employs over 4,000 persons. Three juvenile weeklies with a combined circulation of 750,000, a popular monthly for Sunday-school teachers, and the books and periodicals of the Brethren (Dunkers) are published in Elgin. It is the seat of the Northern State hospital for the insane. The assessed valuation of property in 1926 was $14,450,473. Elgin was settled in 1835, and chartered as a city in 1854.

ELGIN AND KINCARDINE, EARLS OF. Thomas Bruce, 7th earl of Elgin (1766–1841), British diplomatist and art collector, was born on July 20, 1766, and in 1771 succeeded his brother in the Scottish peerage as the 7th earl of Elgin (cr. 1633), and 11th of Kincardine (cr. 1647). In 1792 he was appointed envoy at Brussels, and in 1795 envoy extraordinary at Berlin; and from 1799 to 1802 he was envoy extraordinary at the Porte. During his stay at Constantinople he formed the purpose of removing from Athens the celebrated sculptures now known as the Elgin Marbles. His action was censured by some as vandalism, and doubts were also expressed as to the artistic value of many of the marbles; but he vindicated himself in a pamphlet published in 1810, and entitled *Memorandum on the Subject of the Earl of Elgin's Pursuits in Greece.* In 1816 the collection was purchased by the nation for £36,000, and placed in the British Museum, the outlay incurred by Lord Elgin having been more than £50,000. Lord Elgin was a Scottish representative peer for 50 years. He died at Paris on Nov. 14, 1841.

James Bruce, 8th earl of Elgin (1811–1863), British statesman, eldest son of the 7th earl by his second marriage, was born in 1811, and succeeded to the peerage as 8th earl of Elgin and 12th of Kincardine in 1841. He began his official career in 1842 at the age of 30, as governor of Jamaica, where he improved the condition of the negroes and conciliated the planters by working through them. In 1846 Lord Grey appointed him governor-general of Canada. Son-in-law of the popular earl of Durham, he was well received by the colonists, and he set himself deliberately to carry out the Durham policy. His assent to the local measure for indemnifying those who had suffered in the troubles of 1837 led the mob of Montreal to pelt his carriage for the rewarding of rebels for rebellion, as Mr. Gladstone described it. But long before his eight years' term of service expired he was the most popular man in Canada. His relations with the United States, his hearty support of the self-government and defence of the colony, and his settlement of the free-trade and fishery questions, led to his being raised in 1849 to the British peerage as Baron Elgin.

Soon after his return to England in 1854, Lord Palmerston offered him a seat in the cabinet, which he declined. But when, in 1856 the seizure of the "Arrow" by Commissioner Yeh plunged England into war with China, he went as special envoy with the expedition. On reaching Point de Galle he was met by a force summoned from Bombay to Calcutta by the news of the sepoy mutiny at Meerut on May 11. Urgent letters from Lord Canning reached him at Singapore, the next port, on June 3. H.M.S. "Shannon" was at once sent to Calcutta with the troops destined for China, and Elgin himself followed it, when gloomier letters from India reached him. The position in China was not seriously affected by the want of the troops. Elgin sent in his ultimatum to Commissioner Yeh at Canton on the same day, Dec. 12, that he learned of the relief of Lucknow, and soon afterwards he sent Yeh a prisoner to Calcutta. By July 1858, after months of Chinese deception, he was able to leave the Gulf of Pechili with the emperor's assent to the Treaty of Tientsin. He then visited Japan, and obtained less considerable concessions from its government in the Treaty of Yeddo. That visit proved the beginning of British influence in Japan. Unfortunately, the Chinese difficulty was not yet at an end. After tedious disputes with the tariff commissioners as to the opium duty, and a visit to the upper waters of the Yang-tzse, Elgin had reached England in May 1859. But when his brother and the allied forces attempted to proceed to Peking with the ratified treaty, they were fired on from the Taku forts at the mouth of the Peiho. Lord Russell again sent out Elgin as ambassador extraordinary to demand an apology for the attack, the execution of the treaty, and an indemnity for the military and naval expenditure. Sir Robert Napier (afterwards Lord Napier of Magdala) and Sir Hope Grant, with the French, routed the Tatar troops and sacked the Summer Palace, and by Oct. 24, 1860, a convention was made which was "entirely satisfactory to Her Majesty's Government."

Elgin had not been a month at home when Lord Palmerston selected him to be viceroy and governor-general of India. As the first viceroy directly appointed by the Crown, and as subject to the secretary of State for India, Elgin at once gave up all Lord Canning had fought for, in the co-ordinate independence, or rather the stimulating responsibility, of the governor-general, which had prevailed from the days of Clive and Warren Hastings. On the other hand, he loyally carried out the wise and equitable policy of his predecessor towards the Indian feudatories. He did his best to check the aggression of the Dutch in Sumatra, which was contrary to treaty, and he supported Dost Mohammed in Kabul until he entered the then neutral and disputed area of Herat.

Elgin then assembled a camp of exercise at Lahore, and marched a force to the Peshawar border to punish those branches of the Yusufzai tribe who had violated the engagements of 1858. In the midst of this "little war" he died at the hill station of Dharmsala on Nov. 20, 1863.

For his whole career see *Letters and Journals of James, Eighth Earl of Elgin,* ed. Walrond, but corrected by his brother-in-law, Dean Stanley; for the China missions *see* Laurance Oliphant, *Narrative of the Earl of Elgin's Mission to China and Japan;* for the brief Indian administration *see* the *Friend of India* for 1862–63.

Victor Alexander Bruce, 9th earl of Elgin (1849–1917), British statesman, was born on May 16, 1849, the son of the 8th earl. A Liberal in politics, he became first commissioner of works (1886), and subsequently viceroy of India (1894–99). His administration in India was chiefly notable for the frontier risings of 1897–98. The Afridis broke out into a fanatical revolt and through hesitation on the part of the Government were allowed to seize the Khyber pass, necessitating the Tirah expedition. After his return to England he was nominated chairman of the royal commission to investigate the conduct of the South African War; and on the formation of Sir Henry Campbell-Bannerman's ministry in Dec. 1905, he became secretary of State for the colonies. He retired in 1908, and died in 1917.

His son, Edward James Bruce (1881–), who succeeded him as 10th earl, was made chairman of the Carnegie United Kingdom Trust, and in 1925 was lord high commissioner to the Church of Scotland.

ELGINSHIRE: *see* Moray.

ELGON, also known as Masawa, an extinct volcano in British East Africa, cut by 1° N. and 34½° E., forming a vast isolated mass over 40 m. in diameter. The outer slopes are in great measure precipitous on the north, west and south, but fall more gradually to the east. The southern cliffs are remarkable for extensive caves, which have the appearance of water-worn caves on a coast line and have for ages served as habitations for the natives. The higher parts slope gradually upwards to the rim of an old crater, lying somewhat north of the centre of the mass, and measuring some 8 m. in diameter. The highest point of the rim is

about 14,100 ft. above the sea. Steep spurs separated by narrow ravines run out from the mountain, affording the most picturesque scenery. The ravines are traversed by a number of streams, which flow north-west and west to the Nile (through Lake Choga), south and south-east to Victoria Nyanza, and north-east to Lake Rudolf by the Turkwell, the head-stream of which rises within the crater, breaking through a deep cleft in its rim. To the north-west of the mountain a grassy plain, swampy in the rains, falls towards the chain of lakes ending in Choga; towards the north-east the country becomes more arid, while towards the south it is well wooded. The outer slopes are clothed in their upper regions with dense forest formed in part of bamboos, especially towards the south and west, in which directions the rainfall is greater than elsewhere. The lower slopes are exceptionally fertile on the west, and produce bananas in abundance. On the north-west and north the region between 6,000 and 7,000 ft. possesses a delightful climate, and is well watered by streams of ice-cold water. The district of Save on the north is a halting-place for Arab and Swahili caravans going north. On the west the slopes are densely inhabited by small Bantu-Negro tribes, who style their country Masawa (whence the alternative name for the mountain); but on the south and north there are tribes which seem akin to the Gallas. Of these, the best known are the Elgonyi, from whom the name Elgon has been derived. They formerly lived almost entirely in the caves, but many of them have descended to villages at the foot of the mountain. Elgon was first visited in 1883 by Joseph Thomson, who brought to light the cave-dwellings on the southern face. It was crossed from north to south, and its crater reached, in 1890 by F. J. Jackson and Ernest Gedge, while the first journey round it was made by C. W. Hobley in 1896. (E. HEA.)

EL GRECO: *see* THEOTOCOPULI.

ELI, a member of the ancient priesthood founded in Egypt (1 Sam. ii. 27), priest of the temple of Shiloh, the sanctuary of the ark, and also "judge" over Israel. In the history preserved to us he appears in the weakness of extreme old age, unable to control the petulance and rapacity of his sons. While the central authority was thus weakened, the Philistines advanced against Israel, and gained a complete victory in the great battle of Ebenezer, where the ark was taken, and Hophni and Phinehas slain. On hearing the news Eli fell from his seat and died. After these events the sanctuary of Shiloh appears to have been destroyed (*cf.* Jer. vii. 12, xxvi. 6, 9), and the house of Eli settles at Nob (1 Sam. xxi. 1, xxii. 11 *sqq.*, cp. xiv. 3). In the fall of his house later writers saw the fulfilment of the prophecies of judgment uttered in the days of Eli against his corrupt house (1 Sam. ii. 27 *sqq.*, iii. 11 *sqq.*). (*See* further, SAMUEL, BOOKS OF.)

ELIAS, of Çortona (*c.* 1180–1253), disciple of St. Francis of Assisi, was born of the working class, near Assisi. In 1217 he was the head of the Franciscan mission to the Holy Land, and in 1219 St. Francis made him first provincial minister of Syria. When St. Francis was recalled from the East in 1220 he brought Elias with him. Elias played a leading part in the early history of the Franciscans; Francis made him his vicar general in 1221; he was the practical acting superior of the order till Francis' death in 1226, and the actual superior till the general chapter of 1227. In 1232 he was elected minister general, but at the chapter of 1239 he was deposed. During these years he erected the basilica and monastery at Assisi. After his deposition Elias joined the party of Frederick II. and so incurred excommunication. Frederick sent him as ambassador to Constantinople. A small number of friars adhered to him and for these he built a church and monastery at Cortona. On his death-bed he made his submission to the pope. (*See* FRANCIS OF ASSISI, SAINT.)

See E. Lempp, *Frère Elie de Cortone* (1901), who points out the conflict between the *Speculum perfectionis* and the *First Life*, by Thomas of Celano, as to the relations between Elias and Francis. *See* also P. Sabatier, *Examen de la vie de Frère Elie du Speculum Vitae* (1904).

ELIAS LEVITA (1469–1549), Jewish grammarian, was born at Neustadt on the Aisch, Bavaria. He preferred to call himself "Ashkenazi," the German, and bore also the nickname of "Bachur," the youth or student, which latter he gave as a title to his Hebrew grammar. Before the end of the 15th century he went to Italy, living first at Padua, then (1509) at Venice, going in 1513 to Rome, where he found a patron in the learned general of the Augustinian Order, the future cardinal Egidio di Viterbo, whom he helped in his study of the Kabbalah. The storming of Rome by the Constable de Bourbon in 1527 compelled Elias to go to Venice, where he became corrector in the printing-house of Daniel Bomberg. In 1541 and 1542 he lived at Isny, S. Württemberg, where he published several of his writings in the printing-house of the learned pastor Paul Fagius. The last years of his life he spent at Venice. Levita furthered the study of Hebrew in Christian circles by his activity as a teacher and by his writings, his works on Hebrew grammar (*Bachur*, a text-book, 1518; *Harkaba*, an annotated dictionary of irregular word-forms; a Table of Paradigms; *Pirke Elijahu*, a description—partly metrical—of phonetics, and other chapters of the grammar, 1520; his earliest work, a Commentary on Moses Kimḥi's Hebrew Grammar, 1508) being clear and methodical. Amongst his other writings is the first dictionary of the Targumim (*Meturgeman*, 1541) and the first attempt at a lexicon in which much of the treasure of late Hebrew language was explained (*Tishbi*, explanation of 712 new Hebrew vocables, as a supplement to the dictionaries of David Kimḥi and Nathan b. Yeḥiel, 1542). Scientifically most valuable, and of original importance, are the works of Levita on the *Massora;* his Concordance to the Massora (*Sefer Zikhronot* completed in the second revision 1536), and *Massoreth Hamasoreth* (1538; Eng. tr. by Chr. D. Ginsburg, London, 1867). Of his other writings may be mentioned his commentary on Kimḥi's Grammar and Dictionary (in the Bomberg editions 1545, 1546), his German translation of the Psalms (1545) and the *Baba-Buch* (more properly *Buovobuch*, a German recension of the Italian novel *Historia di Buovo d'Antona*, 1508).

See Y. Levi, *Elia Levita und seine Leistungen als Grammatiker* (Breslau, 1888); W. Bacher, "E. Levita's wissenschaftliche Leistungen" in *Z. d. D. M. G.* xliii. (1889), p. 206–272.

ELIE, police burgh, parish and watering-place, Fifeshire, Scotland, on the Firth of Forth. Pop. (1921), 1,507, including the hamlets of Liberty and Williamsburgh. It is 10 m. S. of St. Andrews, but 20 m. distant by the L.N.E.R., which follows the coast. Though it retains some old houses, and the parish church dates from 1639, Elie is mostly modern and is a popular resort, with fine golf and bathing. The royal burgh of Earlsferry (pop. 745) is continuous with Elie, and in its parish. Its charter, granted by Malcolm Canmore, having been burned, was renewed by James VI. The place derived its name from its use by the earls of Fife as a ferry to the opposite shore of Haddington, 8 m. distant. Macduff's cave near Kincraig Point is believed traditionally to have been that in which the thane took refuge from Macbeth.

ÉLIE DE BEAUMONT, JEAN BAPTISTE ARMAND LOUIS LÉONCE (1798–1874), French geologist, was born at Canon, Calvados, on Sept. 25, 1798. In 1835 he was appointed professor of geology at the École des Mines, in succession to Brochant de Villiers, whose assistant he had been in the duties of the chair since 1827. He held the office of engineer-in-chief of mines in France from 1833 until 1847, when he was appointed inspector-general; and in 1861 he became vice-president of the Conseil-Général des Mines and a grand officer of the Legion of Honour. He was a member of the Academy of Berlin, of the Academy of Sciences of France and of the Royal Society of London, a senator of France from 1852, and, from 1853, perpetual secretary of the Academy of Sciences. Élie de Beaumont's theory of the origin of mountain ranges was propounded in a paper read to the Academy of Sciences in 1829, and afterwards elaborated in his *Notice sur le système des montagnes* (3 vols., 1852). According to his view, all mountain ranges parallel to the same great circle of the earth are of strictly contemporaneous origin, and between the great circles a relation of symmetry exists in the form of a pentagonal *réseau* (*see* criticism by W. Hopkins in *Quart. Journ. Geol. Soc.*, 1853). Probably the best service Élie de Beaumont rendered to science was in the preparation with Dufrénoy (*q.v.*) of the great geological map of France. After his superannuation at the École des Mines he continued to super-

intend the issue of the detailed maps almost until his death at Canon on Sept. 21, 1874. His academic lectures for 1843–44 were published in 2 vols., 1845–49, under the title *Leçons de géologie pratique.*

A list of his works was published in the *Ann. des Mines,* vol. vii. 1875, p. 259.

ELIJAH, a prophet of Tishbeh in Gilead, contemporary with Ahab king of Israel (*c.* 876–853 B.C.), and the hero of the following stories preserved in the Books of Kings: (*a*) *1 Kings xvii., xviii.*—Of the marvellous acts of Elijah, and of his triumph over the prophets of Baal: how he brought a three years' drought upon Israel, and, during the famine caused by the drought, was himself miraculously fed, first by ravens, and, later, by a widow of Zarephath, whose food he miraculously multiplied and whose son he raised from the dead; how he defied the king of Israel, challenged the prophets of Baal to a religious contest, and, having defeated them by the aid of Yahweh his God, slew them with his own hand; finally, how he brought the drought to an end. (*b*) *1 Kings xix.*—Of the despondency of Elijah: how he fled from the wrath of Jezebel to Beersheba, was there visited by an angel, miraculously fed, and commanded to go to Horeb the mount of God; how he came thither and waited in a cave; how Yahweh made himself known in a "still small voice," and in answer to Elijah's complaints against his people commissioned him to anoint Hazael, Jehu, and Elisha as agents of (their?) destruction; how Elijah called (or, as Gunkel believes, magically compelled) Elisha to follow him. (*c*) *1 Kings xxi.*—Of his denunciation of Ahab: how Ahab and Jezebel encompassed the death and obtained the vineyard of Naboth of Israel, and how, in the very flush of Ahab's guilty satisfaction, Elijah suddenly appeared proclaiming the wrath of Yahweh against the thing which Ahab had done and foretelling that Ahab's blood should be shed in the very place where he had shed the blood of Naboth. (*d*) *2 Kings i.*—Of Elijah's hostility to foreign gods, and of the deference demanded by him: how Ahaziah, king of Israel, sent messengers to the temple of the god of Ekron to enquire whether he would recover from the effects of a fall; how Elijah turned back the messengers with the message that the king would die; how the king twice sent companies of soldiers to arrest Elijah, and how they were destroyed by fire from heaven; how, when a third company approached him with complete deference, Elijah went with them to the king, told the king that he would die, and how the king accordingly died. (*e*) *2 Kings ii.,* 1–18.—Of the passing of Elijah: how, divinely prompted, he went from Gilgal to Bethel, from Bethel to Jericho; how Elisha refused to leave him, though at each stage of his journey "sons of the prophets" warned him that Elijah was to be taken away, and Elijah himself exhorted him to stay behind; how, with a blow of his folded mantle, Elijah divided the waters of Jordan; how, beyond Jordan, Elijah asked Elisha to choose one last favour, and, when Elisha requested that he might inherit a first-born's portion of Elijah's power, replied that this gift could only be given if he actually saw his master taken away; how Elisha saw chariots and horses of fire and Elijah snatched by a whirlwind to heaven, took up Elijah's mantle, passed over Jordan dryshod by its magic power; was received by the sons of the prophets at Jericho as Elijah's true successor; and how the sons of the prophets sought in vain for three days for Elijah.

Some details of these stories are corroborated by evidence from other sources (the occurrence of a drought at this time, *cf.* Menander, *ap.* Josephus *Antiq.* viii., 13.2; the name of Ahab's wife and her difference with Elijah, *cf.* 1 Kings xvi. 31; 2 Kings ix. 36; the toleration of Baal worship by the house of Omri, 2 Kings x.; the murder of Naboth, 2 Kings ix., 26); some are inconsistent with other evidence (*e.g.,* Jezebel did not murder all the prophets of Yahweh, *cf.* 1 Kings xxii., 6; 2 Kings ii., 3, etc.; if Ahab had abandoned the worship of Yahweh he would not have called his sons "Ahaziah" and "Jehoram"; according to 2 Kings x., 19, *seq.* the massacre of the prophets of Baal was made not by Elijah but by Jehu); some have many parallels in secular folk-lore (*e.g.,* the ministering ravens, the unfailing cruse, the magic mantle, the mysterious appearances and disappearances); some stories are remarkably like those told of other Biblical heroes (*e.g.,* Moses and Elisha, *cf.* Exod. xiv., 21 *seq.* xxxiii., 22, Deut. xxxiv., 5 *seq.,* Josh. iii., 16, 2 Kings iv.). In short, the Elijah stories are not genuine biography but folk-tales, some of which were told of other heroes also. Behind the folk-tales stands a historical person, who evidently made a deep impression upon the minds of his contemporaries, but he is shrouded in mist, and we can no longer see him clearly. That he was a religious enthusiast who lived in Ahab's time, and was violently opposed to royal oppression and to the toleration of foreign cults in Israel, even when such toleration was a political necessity, is as much of his story as can now be recovered. Was he a monotheist? What were his theological beliefs? How far did he use political means to gain his ends? Is the story of his visit to Horeb an idealization of some attempt he made to stir up the Arabian tribes to war against Israel? To such questions no answer can be given.

"In solitary grandeur did this prophet tower conspicuously over his time; legend, and not history, could alone preserve the memory of his figure. There remains a vague impression that with him the development of Israel's conception of Jehovah entered upon a new stadium, rather than any data from which it can be ascertained wherein the contrast of the new with the old lay" (Wellhausen, *Hist. of Israel.* E. T., p. 462).

References to the original stories, and to later legends, about Elijah occur in 2 Chron. xxi., 12 *seq.,* Mal. iv., 5 *seq.,* Ecclus, xlviii., 1–12; Matt. xi. 14, xvi. 14, Luke ix. 8, John i. 21, Rev. xi. 6. Hist.* vol. iii., pp. 364–72.

(F. S. M.)

ELIJAH WILNA or **ELIJAH BEN SOLOMON,** best known as the Gaon Elijah of Wilna (1720–1797), a noted Talmudist who hovered between the new and the old schools of thought. Orthodox in practice and feeling, his critical treatment of the rabbinic literature prepared the way for later scientific investigations. He was one of the first to distinguish the various strata in rabbinic records; to him was due the revival of interest in the older Midrash (*q.v.*) and in the Palestinian Talmud (*q.v.*). As an ascetic, he opposed the emotional mysticism known as the new Hassidism.

See S. Schechter, *Studies in Judaism* (1896). For his voluminous writings see *Jewish Encyclopedia,* v. 134.

ELIOT, SIR CHARLES NORTON EDGCUMBE (1864–), British diplomatist and writer, was educated at Cheltenham and Balliol college, Oxford, and became a fellow of Trinity college. He entered the diplomatic service in 1886 and acted as chargé d'affaires in Morocco in 1892–93, in Bulgaria, 1895 and in Serbia, 1897. In Jan. 1901 he was appointed high commissioner of the British East Africa Protectorate, but resigned in Jan. 1904, being opposed to the grant of a concession to the East Africa Syndicate, which he held to be detrimental to genuine colonization. For some years he abandoned the diplomatic service, but in Aug. 1918 he was named high commissioner in Siberia, and in Nov. 1919 became ambassador to Japan, being thereupon sworn of the Privy Council. He was created G.C.M.G. in 1923, and in 1926, the year of his retirement, was appointed a member of the Japanese Imperial Academy, being the first foreigner to receive this honour.

Eliot's works include: *Turkey in Europe* (1900); *Letters from the Far East* (1907); *Hinduism and Buddhism* (1921). He wrote also *The East Africa Protectorate* (1905), and *A Finnish Grammar* (1890).

ELIOT, CHARLES WILLIAM (1834–1926), American educator and publicist, the son of Samuel Atkins Eliot (1798–1862), who was mayor of Boston, representative in Congress and in 1842–53 treasurer of Harvard college, was born in Boston on March 20, 1834. He graduated in 1853 at Harvard, where he was successively tutor in mathematics (1854–58) and assistant professor of mathematics and chemistry (1858–63). He studied chemistry and foreign educational methods in Europe (1863–65); was professor of analytical chemistry in the newly established Massachusetts Institute of Technology (1865–69), although absent 14 months in Europe in 1867–68; and in 1869 was elected president of Harvard university, a choice remarkable at once because of his

youth and because of his being a layman and scientist. This position he held until 1909, from which year until his death, 17 years later, at the age of 92, he was president emeritus. With Johns Hopkins university, Harvard, in the early years of Eliot's presidency, led in organization and increased efficiency of graduate work. The elective system, which has spread far, although not originated by President Eliot was thoroughly established by him, and is only one of many innovations which he successfully championed. The raising of entrance requirements, which led to a corresponding raising of the standards of secondary schools, and the introduction of an element of choice in these entrance requirements, which allowed a limited election of studies to secondary pupils, became national tendencies primarily through President Eliot's potent influence. As chairman of a national committee of ten (1890) on secondary school studies, he urged the abandonment of brief disconnected "information" courses, the correlation of subjects taught, the equal rank in college requirements of subjects in which equal time, consecutiveness and concentration were demanded, and a more thorough study of English composition; and to a large degree he secured national sanction for these reforms and their working out by experts into a practicable and applicable system. He laboured to unify the entire educational system, minimize prescription, do away with monotony and introduce freedom and enthusiasm; and he emphasized the need of special training for special work. He contended that secondary schools maintained by public funds should largely shape their courses for the benefit of students whose education goes no further than high schools, and should not be mere training schools for the universities.

President Eliot was long a leader in the movement for the introduction of business methods in government work, and in Dec. 1908 was elected president of the National Civil Service Reform League. He was offered the post of ambassador to England by President Taft in 1909, but preferred to serve his country in a private capacity at home. The same position was tendered him in 1913 by President Wilson and again declined. By writing and speaking he continued to take an active part in all the important public questions of the day. His theories as to needed changes toward the concrete and practical in education had great influence upon American schools. He aided vocational education by his continued insistence upon the training of the senses of sight, hearing and touch, as being the sources of the best part of knowledge. In 1914 he was elected president of the American Association for the Advancement of Science. In his educational writings he maintained that the traditional systems had dealt too exclusively with language and literature. In 1916, however, he was awarded a gold medal by the American Academy of Arts and Letters for his services to literature in his educational work. In the field of religion he was an authoritative spokesman for the Unitarian faith. In his books *The Religion of the Future* (1909) and *Twentieth Century Christianity* (1914) he emphasized freedom in place of authority; he held that the teaching of Jesus had been "the undying root of all the best in human history since He lived," and that He would be the supreme teacher in the religion of the future, the outcome of which would be the brotherhood of man. President Eliot gave much attention to labour problems and declared that "profit-sharing, combined with co-operative management, in which the employees take active and reasonable part, with co-operative care of health, education and happiness of employees, and with full knowledge by employees of the employers' account, is the only road to industrial peace." He condemned the closed shop, limited output by labour and uniform hours and wages. The settling of industrial strife he considered the next important thing after the establishment of a league of nations. He was a strong supporter of President Wilson's administration; he favoured prohibition as a war measure, and later as an amendment to the Constitution. He wrote in favour of military training after the Swiss method, but maintained that, after a league of nations was formed, no country should be allowed to have an army "whose officers have entered for life the profession of soldier." In 1920 he was an active worker for the Democratic party because he regarded the immediate adoption of the Covenant of the League of Nations as a moral obligation. He died at Northeast Harbor, Me., on Aug. 22, 1926.

The "unique place in American public life" occupied by President Eliot has been well described by William Allan Neilson, president of Smith college: "For 40 years the head of a great university, he exercised on all classes of his countrymen an influence far beyond that of the usual academic dignitary. During the latter part of his presidency, and still more after he became emeritus, he was looked up to by hundreds of thousands of his fellow-citizens as a guide not merely in educational matters, but in all the great questions that have agitated the public mind, political, industrial, social and moral. Other leaders of opinion have come and gone, and some for a time have been more conspicuous; but it is impossible to name a figure who so continuously dominated our intellectual horizon for so long a period."

President Eliot's writings include *A Compendious Manual of Qualitative Chemical Analysis* with F. H. Storer (1869), many times reissued and revised; *The Happy Life* (1896); *American Contributions to Civilization, and Other Essays and Addresses* (1897); *Educational Reform, Essays and Addresses 1869–1897* (1898); *Charles Eliot, Landscape Architect* (1902), a biography of one of his sons; *More Money for the Public Schools* (1903); *Four American Leaders* (1906), chapters on Franklin, Washington, Channing and Emerson; *University Administration* (1908); *The Durable Satisfactions of Life* (1910); *The Conflict Between Individualism and Collectivism in a Democracy* (1910); *The Road Toward Peace* (1915); and *A Late Harvest* (1924). His annual reports as president of Harvard were notable contributions to the literature of education, and he delivered numerous public addresses, many of which have been reprinted.

See "President Eliot's Administration," by various writers, a summary of his work at Harvard in 1869–94, in the *Harvard Graduates' Magazine*, vol. ii., pp. 449–504 (1894); E. H. Cotton, *The Life of Charles W. Eliot* (1926); and *Charles W. Eliot, the Man and His Beliefs*, edited, with a biographical study, by W. A. Neilson (1926).

ELIOT, GEORGE, the pen-name of the famous English writer, *née* Mary Ann (or Marian) Evans (1819–1880), afterwards Mrs. J. W. Cross, born at Arbury farm, Chilvers Coton, Warwickshire, on Nov. 22, 1819. Her father, Robert Evans, was the agent of Francis Newdigate, and the first 21 years of her life were spent on the Arbury estate. She received an ordinary education till the age of 17, when her mother's death and the marriage of her elder sister called her home in the character of housekeeper. She was thus able to work without pedantic interruptions at German, Italian and music, and to follow her own excellent taste in reading. Marian Evans was subdued all through her youth by a severe religious training which, while it pinched her mind and crushed her spirit, attracted her idealism by the very hardness of its counsels. But when her father moved to Coventry in 1841 she made new friends, Mr. and Mrs. Charles Bray and Charles Hennell. Bray had written works on the *Education of the Feelings*, the *Philosophy of Necessity*, and the like. Hennell had published in 1838 *An Enquiry Concerning the Origin of Christianity*. Miss Evans, then 22, absorbed immediately these unexpected and, at that time, daring habits of thought, and narrowly avoided a breach with her father, a churchman of the old school. George Eliot was never orthodox again; she remained throughout life a rationalist. But she had learnt the evangelical point of view; she knew—none better—the strength of religious motives; vulgar doubts of this fact were as distasteful to her as they were to Huxley. Her books abound in tributes to Christian virtue, and one of her own favourite characters was Dinah Morris in *Adam Bede*.

She began, in 1844, the translation of Strauss's *Leben Jesu*. On the death of her father in 1849 she went abroad for some time. In 1851 she accepted the assistant-editorship of the *Westminster Review*. For a while she had lodgings at the offices of the *Review* in the Strand, London. She wrote several notable papers, and became acquainted with Herbert Spencer, Carlyle, Harriet Martineau, Francis Newman, George Henry Lewes and others. Her friendship with Lewes led to a closer relationship which she regarded as a marriage. Among the many criticisms passed upon this step (Lewes had a wife living at the time), no one has denied her courage or her tact in a difficult position. The union was a singularly happy one. Lewes was devoted to her, appreciated her

genius and did his best to shield her from every kind of rough contact with the world. In later days he perhaps went too far in this direction, for she was never allowed to see adverse criticism which might have wounded her sensitive nature. She was over-sensitive, liable to fits of depression and at no time robust in health. A woman of wide culture and masculine understanding, she yet had an excessively feminine temperament. The lovers made a delightful tour in Germany which Marian Evans thoroughly enjoyed. Lewes was preparing his *Life of Goethe,* and they saw many important people in Berlin and Weimar. This journey made the definite break with her former life, and undoubtedly gave her fresh inspiration. On their return to England, Lewes and she established joint housekeeping. They moved frequently, but always maintained a circle of friends. Many descriptions exist of George Eliot's receptions; they became in course of time serious affairs, with Lewes as master of ceremonies. Admission was very highly prized and, in later days, not too easy. The house specially associated with the Leweses was 21 North Bank, Regent's Park, which they took in 1863.

But at this time fame had not been achieved. Marian Evans was occupied with translations—Feuerbach's *Essence of Christianity* (1854); Spinoza's *Ethics* (never published)—and with articles for the *Westminster Review* and the *Saturday Review.* Presently she confided to Lewes that she was seeking relaxation in writing fiction. The story was "The Sad Fortunes of the Reverend Amos Barton," the first of the *Scenes from Clerical Life* (2 vols., 1858); it appeared in *Blackwood's Magazine* as the work of "George Eliot," and Marian Evans strictly hid her identity for many years. *Scenes from Clerical Life* won the praise of Dickens, but triumphant success only came with *Adam Bede* (1859), followed in 1860 by *The Mill on the Floss,* and in 1861 by *Silas Marner.* Neither of these met with the great immediate success of *Adam Bede.* This group of novels remains for most readers George Eliot's most valuable contribution to English literature and to English social history. She was writing of the Warwickshire countryside, of the impressions gathered in her early life when distractions were few and her mind and vision still unimpeded by the theories and the philosophy of the *Westminster Review* circles. In the earlier and better half of *The Mill on the Floss* she drew, with little disguise, on her own life and her relations with her brother Isaac, and in Adam Bede and Caleb Garth there is something of her father. In the opinion of many good judges the first of the series, *Scenes from Clerical Life,* is George Eliot's most enduring work. Leslie Stephen (*Dict. Nat. Biog. s.v.* Cross) wrote: "In some respects, the *Scenes from Clerical Life* were never surpassed by their author. Their unforced power, their pathos, and the sympathetic appreciation of the old-fashioned life by a large intellect give them a singular charm."

George Eliot was now famous. Smith and Elder offered her £10,000 for the copyright of her next book; she accepted £7,000 for its appearance in the *Cornhill Magazine.* The book was *Romola* (1862–63), and with it begins her second period. She spent a month in Florence (May–June 1861) seeking material, and before she began to write in the autumn she had amassed an imposing pile of notes and memoranda on the history of Florence and the times of Savonarola. The book has perhaps been unduly disparaged; the truth is that all her later work, with the possible exception of *Middlemarch,* suffers, for modern readers, by comparison with the powerful and deeply felt earlier stories, when she was driven to write by an overpowering need for self expression. By her contemporaries they were eagerly looked for in a great age of the novel. The works following *Romola* are *Felix Holt* (1866), a political novel; *The Spanish Gypsy* (1868), a drama in blank verse, written under strong positivist influence; *The Legend of Jubal and other Poems* (1874); *Middlemarch* (1872), a long novel, which is a masterly psychological analysis of middle class life; *Daniel Deronda* (1876), a strong intellectual plea against anti-Jewish prejudice; and *The Impressions of Theophrastus Such,* a collection of essays (1879). This great body of work between 1866 and 1879, was the accomplishment of a powerful intellect and shows an extraordinarily acute perception of human nature.

George Eliot wrote for a serious public. She herself demanded too strenuously from the very beginning an aim, more or less altruistic, from every individual; and as she advanced in life this claim became the more imperative, till at last it overpowered her art, and transformed a great delineator of humanity into an eloquent observer with far too many personal prejudices. Joy was lost in the consuming desire for strict accuracy; her genius became more and more speculative, less and less emotional. The highly-trained brain suppressed the impulsive heart. Little of her verse, beyond the famous lines "O, might I join the choir invisible," passed into current thought; her best work was done in prose.

Throughout these years she was sustained and stimulated by the companionship of Lewes. At the end of 1876 they settled at Witley, near Godalming, and on Nov. 28, 1878, Lewes died. George Eliot wrote no more. She saw hardly anyone, and devoted herself to preparing Lewes's unfinished work for press. In her widowhood—it was a real widowhood—she was helped in her affairs by a friend of long standing, J. W. Cross, and married him, at St. George's, Hanover square, on May 6, 1880. Early in December they took a house in London, No. 4, Cheyne Walk. There she died on Dec. 22, 1880.

See the *Life of George Eliot,* edit. by J. W. Cross (3 vols., 1885–87); Sir Leslie Stephen, *George Eliot,* in the "English Men of Letters" series (1902); Oscar Browning, "Great Writers" series (1890), with a bibliography by J. P. Anderson; Mathilde Blind, "Eminent Women" series, a later edition of which also contains a bibliography (Boston, Mass., 1904); A. W. Ward in *Camb. Hist.,* vol. xiii. (1916); Elizabeth Haldane, *George Eliot and her Times* (1927); and Arthur Paterson, *George Eliot's Family Life and Letters* (1928).

ELIOT, SIR JOHN (1592–1632), English statesman, was born at Port Eliot, Cornwall, and educated at Exeter college, Oxford. He then studied law, and spent some years in travel on the continent before he entered parliament as M.P. for St. Germans in 1614. In 1618 he was knighted, and next year through the patronage of Buckingham he obtained the appointment of vice-admiral of Devon, with large powers for the defence and control of the commerce of the county. In 1623 he succeeded by a clever but dangerous manoeuvre in entrapping the famous pirate John Nutt, who had for years infested the southern coast, inflicting immense damage upon English commerce. The pirate, having a powerful protector at court in Sir George Calvert, the secretary of State, was pardoned; while the vice-admiral was flung into the Marshalsea, and detained there nearly four months.

A few weeks after his release Eliot was elected member of parliament for Newport (Feb. 1624). On the 27th he delivered his first speech, in which he at once revealed his great powers as an orator, demanding boldly that the liberties and privileges of parliament, repudiated by James I. in the former parliament, should be secured. In the first parliament of Charles I., in 1625, he urged the enforcement of the laws against the Roman Catholics. Meanwhile he had continued the friend and supporter of Buckingham, but the bad faith with which both he and the king continued to treat the parliament, alienated Eliot completely from the administration. Distrust of his former friend developed into a conviction of his criminal ambition and treason to his country. Returned in 1626 as member for St. Germans, Eliot found himself the leader of the House. He immediately demanded an inquiry into the disaster at Cadiz. On March 27 he made an open and daring attack upon Buckingham and his evil administration. He was not intimidated by the king's threatening intervention on the 29th, and persuaded the House to defer the actual grant of the subsidies and to present a remonstrance to the king, declaring its right to examine the conduct of ministers. On May 8, he was one of the managers who carried Buckingham's impeachment to the Lords, and on the 10th he delivered the charges against him, comparing him in the course of his speech to Sejanus. Next day Eliot was sent to the Tower. On the Commons declining to proceed with business as long as Eliot and Sir Dudley Digges (who had been imprisoned with him) were in confinement, they were released, and parliament was dissolved on June 15. Eliot was dismissed from his office of vice-admiral of Devon, and in 1627 he was again imprisoned for refusing to pay a forced loan, but liberated shortly before the assembling of the parliament of 1628,

to which he was returned as member for Cornwall. He joined in the resistance now organized to arbitrary taxation, was foremost in the promotion of the Petition of Right, continued his outspoken censure of Buckingham, and after the latter's assassination in August, led the attack in the session of 1629 on the ritualists and Arminians.

PROSECUTOR OF BUCKINGHAM

In February the question of the right of the king to levy tonnage and poundage came up for discussion; and on the king ordering an adjournment of parliament, the speaker, Sir John Finch, was held down in the chair while Eliot's resolutions against illegal taxation and innovations in religion were read to the House by Holles (*q.v.*). In consequence, Eliot, with eight other members, was imprisoned on March 4, in the Tower. He refused to answer in his examination, relying on his privilege of parliament, and on Oct. 29 was removed to the Marshalsea. On Jan. 26, he appeared at the bar of the king's bench, with Holles and Valentine, to answer a charge of conspiracy to resist the king's order, and, refusing to acknowledge the jurisdiction of the court, he was fined £2,000 and ordered to be imprisoned during the king's pleasure and till he had made submission. This he steadfastly refused. Eliot's confinement in the Tower was exceptionally severe. Charles hated him as the prosecutor and bitter enemy of Buckingham; "an outlawed man," he described him, "desperate in mind and fortune."

In prison Eliot wrote several works, his *Negotium posterorum*, an account of the parliament in 1625; *The Monarchie of Man*, a political treatise; *De jure majestatis, a Political Treatise of Government;* and *An Apology for Socrates*, his own defence. In Oct. 1632 ill-health drove him to petition Charles for permission to go into the country, but leave could only be obtained at the price of submission and was finally refused. He died on Nov. 27, 1632. When his son requested permission to move the body to Port Eliot, Charles returned the curt refusal: "Let Sir John Eliot be buried in the church of that parish where he died." The manner of Eliot's death had more effect, probably, than any other single incident in embittering and precipitating the dispute between king and parliament; and the sacrifice of a man actuated originally by no antagonistic feeling against the monarchy or the church, is the surest condemnation of the king's policy and administration.

Eliot married Rhadagund, daughter of Richard Gedie of Trebursye in Cornwall, by whom he had five sons, from the youngest of whom Granville John Eliot, the present earl of St. Germans, is descended, and four daughters.

The *Life of Sir J. Eliot*, by J. Forster (1864), is supplemented and corrected by Gardiner's *History of England*, vols. v.–vii., and the article in the *Dict. of Nat. Biog.*, by the same author. Eliot's writings, together with his Letter-Book, have been edited by Dr. Grosart.

ELIOT, JOHN (1604–1690), American colonial clergyman, known as the "Apostle to the Indians," was born probably at Widford, Hertfordshire, England, where he was baptized on Aug. 5, 1604. He was the son of Bennett Eliot, a middle-class farmer, and graduated at Jesus college, Cambridge, in 1622. He probably entered the ministry of the Established Church, but there is nothing definitely known of him until 1629–30, when he became an usher at the school of the Rev. Thomas Hooker, at Little Baddow, near Chelmsford. Apparently influenced by him to become a Puritan, he emigrated to America in the autumn of 1631, where he settled first at Boston, assisting for a time at the First Church. In Nov. 1632 he became "teacher" to the church at Roxbury, with which his connection lasted until his death. There he married Hannah Mulford, who had been betrothed to him in England, and who became his constant helper.

Inspired with the idea of converting the Indians, his first step was to perfect himself in their dialects, and with the aid of a young Indian he translated the Ten Commandments and the Lord's Prayer; in 1646 he first preached to them in their own tongue at Nonantun (Newton). The conversion of a number of Indians caused the Massachusetts general court to set aside land for their residence and in July 1649 Parliament incorporated the "Society for the Propagation of the Gospel in New England," which henceforth supported and directed the work inaugurated by Eliot. In 1651 the Christian Indian town founded by Eliot was removed from Nonantun to Natick, where Eliot continued to preach throughout his life. A second town under his direction was established at Ponkapog (Stoughton) in 1654, in which he had the assistance of Daniel Gookin (*c.* 1612–87). His success was duplicated in Martha's Vineyard and Nantucket by the Mayhews, and by 1674 the unofficial census of the "praying Indians" numbered 4,000. King Philip's war (1675–76) was a staggering blow to all missionary enterprise; and although few of the converted Indians proved disloyal, it was some years before adequate support could again be enlisted. Yet at Eliot's death, which occurred at Roxbury on May 21, 1690, the missions were at the height of their prosperity.

Of wide influence and lasting value was Eliot's work as a translator of the Bible and various religious works into the Massachusetts dialect of the Algonkin language. The *Catechism*, published in 1653 at Cambridge, Mass., was the first book to be printed in the Indian tongue. The New Testament was issued in 1661, and the Old Testament two years later. With the assistance of his sons he completed his well known *Indian Grammar Begun* (1666). *The Indian Primer* and a translation of the *Larger Catechism* followed in 1669. In 1671 Eliot printed in English *Indian Dialogues*, followed in 1672 by *Logick Primer*, both of which were intended for the instruction of the Indians in English. A curious treatise on government entitled *The Christian Commonwealth* was published in 1659. His *Harmony of the Gospels* (1678) was a life of Jesus Christ.

See Williston Walker's *Ten New England Leaders* (1901); the "Life of John Eliot," by Convers Francis, in *Sparks' American Biography* (vol. v., 1836); another by N. Adams (1847); and a sketch in Cotton Mather's *Magnalia* (London, 1702). *See* the chapter on "The Indian Tongue and its Literature," by J. H. Trumbull, in vol. i. of the *Memorial History of Boston* (1882). *See* also the *Cambridge History of American Literature* vol. i., pp. 390–393 (1917).

ELIS or **ELEIA,** an ancient district of southern Greece, bounded on the N. by Achaea, E. by Arcadia, S. by Messenia, and W. by the Ionian Sea. The local form of the name was Valis, or Valeia, and its meaning, in all probability, "the lowland." In its physical constitution Elis is continuous with Achaea and Arcadia; its mountains are offshoots of the Arcadian highlands, and its principal rivers are fed by Arcadian springs. From Erymanthus in the north, Skollis (now known as Mavri and Santameri in different parts of its length) stretches toward the west, and Pholoe along the eastern frontier; in the south a prolongation of Mt. Lycaeon bore in ancient times the names of Minthe and Lapithus, which have given place respectively to Alvena and to Kaiapha and Smerna. These mountains are well clothed with vegetation, and present a pleasing contrast to the picturesque wildness of the parent ranges. Towards the west they sink into what was one of the richest tracts in Peloponnesus. Except at the rocky promontories of Chelonatas (now Chlemutzi) and Ichthys (now Katakolo), the coast lies low, with stretches of sand in the north and lagoons and marshes towards the south. During the summer when they communicate with the sea, these lagoons yield a rich harvest of fish but the inhabitants are then almost driven from the coast by the mosquitoes. The district for administrative purposes forms part of the nome of Elis and Achaea (*see* GREECE).

Elis was divided into three districts—Hollow or Lowland Elis, Pisatis, the territory of Pisa, and Triphylia, the "country of the three tribes." (1) *Hollow Elis*, the largest and most northern of the three, was watered by the Peneus and its tributary the Ladon, whose united stream forms the modern Gastouni. It included not only the champaign country originally designated by its name, but also the mountainous region of Acrorea, occupied by the offshoots of Erymanthus. Besides the capital city of Elis, it contained Cyllene, an Arcadian settlement on the sea-coast, whose inhabitants worshipped Hermes under the phallic symbol; Pylus, at the junction of the Peneus and the Ladon, which, like so many other places of the same name, claimed to be the city of Nestor, and the fortified frontier town of Lasion, the ruins of which are

still visible at Kuti, near the village of Kumani. The district was famous in antiquity for its cattle, horses and byssus.

(2) *Pisatis* extended south from Hollow Elis to the right bank of the Alpheus, and was divided into eight departments called after as many towns. From ancient times it has been disputed whether Pisa, which gave its name to the district, had ever been a city, or was only a fountain or a hill. By far the most important spot in Pisatis was the scene of the Olympic games, on the northern bank of the Alpheus (*see* OLYMPIA).

(3) *Triphylia* stretches south from the Alpheus to the Neda, which forms the boundary towards Messenia. Of nine towns mentioned by Polybius, Lepreum and Macistus gave their names to southern and northern Triphylia. The former had a strongly independent population, and took every opportunity of resisting the supremacy of the Eleans. In the time of Pausanias it was decadent, and possessed only a brick-built temple of Demeter; but its outer walls still exist near the village of Strovitzi.

The original inhabitants of Elis were called Caucones and Paroreatae. Under the title of Epeians they are mentioned as setting out for the Trojan War, and as living in constant hostility with the Pylians. At the close of the 11th century B.C. the Dorians invaded the Peloponnesus, and Elis fell to the share of Oxylus and the Aetolians, who, amalgamating with the Epeians, formed a powerful kingdom in the north of Elis. After this many changes took place, till only three tribes, Epeians, Minyae and Eleans, remained independent. Before the end of the 8th century B.C., however, the Eleans had established supremacy over the whole country with the right of celebrating the Olympic games, which had formerly been the prerogative of the Pisatans. The attempts which this people made to recover their lost privilege ended in the total destruction of their city by the Eleans in 572 B.C. Till the Peloponnesian War, Elis remained undisturbed. Though Elis sided at first with Sparta, that power, jealous of the increasing prosperity of its ally, picked a quarrel. At the battle of Mantinea (418 B.C.) the Eleans fought against the Spartans, who, as soon as the war came to a close, took vengeance upon them by depriving them of Triphylia and the towns of the Acrorea. The Eleans made no attempt to re-establish their authority till after the battle of Leuctra (371 B.C.), when they might have effected their purpose had not the Arcadian confederacy come to the assistance of the Triphylians. In 366 B.C. hostilities broke out and, though the Eleans were at first successful, their capital very nearly fell and they applied for assistance to the Spartans, who forced the Arcadians to recall their troops from Elis. The result was the restoration of their territory to the Eleans, with the right of holding the Olympic games. During the Macedonian supremacy in Greece they sided with the victors, but refused to fight against their countrymen. After the death of Alexander they renounced the Macedonian alliance and later joined the Aetolian League, persistently refusing to identify themselves with the Achaeans. When the whole of Greece fell under the Roman yoke, the sanctity of Olympia secured for the Eleans a certain amount of indulgence. The games continued to attract large numbers of strangers, until they were finally put down by Theodosius in 394, two years before the Gothic invasion under Alaric. In later times Elis fell successively into the hands of the Franks and the Venetians, under whose rule it recovered to some extent its ancient prosperity.

See Pauly Wissowa, *Realencyklopädie, s.v.*

ELIS, the chief city of the ancient Greek district of Elis, on the ridge now called Kalaskopi, south of the river Peneus, where it passes from the mountainous Acrorea into the lowland. It was traditionally founded by Oxylus, leader of the Aetolian immigrants, whose statue stood in the market-place. In 471 B.C. it incorporated various small hamlets, whose inhabitants took up their abode in the city. As all the athletes in the Olympic games were obliged to undergo a month's training in the city, its gymnasiums were among its principal institutions. Other objects of interest are described in detail by Pausanias, but no buildings can be identified, the only remains visible dating from Roman times. On the acropolis was a temple of Athena, with a gold and ivory statue by Pheidias. The history of the town follows that of the country (*q.v.*). In 399 B.C. it was occupied by Agis, king of Sparta. The acropolis, now called Palaeopolis, was fortified in 312 by Telesphorus, the admiral of Antigonus, but it was shortly afterwards dismantled by Philemon, another of his generals.

Curtius, *Peloponnesus* (1851–52); Schiller, *Stämme und Staaten Griechenlands;* C. Bursian, *Geographie von Griechenland* (1868–72); P. Gardner, "The Coins of Elis," *Num. Chr.* (1879).

ELIS, PHILOSOPHICAL SCHOOL OF. This school was founded by Phaedo, a pupil of Socrates. It existed for a very short time and was then transferred by Menedemus to Eretria, where it became known as the Eretrian school. Its chief members beside Phaedo, were Anchipylus, Moschus and Pleistanus (*see* PHAEDO and MENEDEMUS).

ELISHA, a prophet, reputed successor of Elijah (*q.v.*). He is a much more shadowy figure than Elijah, though he occupies a larger space in the Books of Kings. The stories there told about him, which seem to have come from several sources and not to be in their original order (*e.g.*, 2 Kings viii. 1–6 should precede v. 26 *seq.*), may be divided into two groups: (*a*) Anecdotes of his private life, showing how, except when he caused two she-bears to fall upon 42 boys who insulted him (ii. 23–25), and transferred Naaman's leprosy to his own servant Gehazi (v. 20, *seq.*), he used the miraculous power he had inherited from Elijah (ii. 9, *seq.*) in works of homely beneficence; how he made wholesome a poisonous spring (ii. 19, 20) and a poisonous soup (iv. 38.–41); saved an insolvent widow from selling her sons into slavery by miraculously increasing her oil (iv. 1–7); cured the sterility of a barren woman, raised to life her dead son, and induced the king to right her wrongs (iv. 8–37, viii. 1–6); fed 100 men with 20 loaves and had bread to spare (iv. 42–44); caused a borrowed axe-head to float upon the water into which it had fallen (vi. 1–7); gave a vision of the heavenly host to his terrified servant (vi. 17); and by the power of his dead bones raised a corpse to life (xiii. 21). These are simple folk-tales, some of which are also told of Elijah and of other Old Testament heroes (*cf.* Genesis xviii. 10, *seq.*, Exod. xv. 23, 24). The place names contained in the stories (Jericho, ii. 18 *seq.;* Bethel, ii. 23; Carmel, ii. 25; iv. 25; Shunem, iv. 8; Gilgal, iv. 38; Dothan, vi. 13) may indicate where the stories originated. Several are places where "sons of the prophets" lived. (*b*) The second group consists of stories of the public life of Elisha, showing how he earned the title "the chariots and horsemen of Israel" (2 Kings, xiii. 14); how, during a campaign against Moab, he saved the armies of Israel and Judah from dying of thirst (iii. 10–24); how he gave the signal for Jehu's rebellion against the house of Omri by sending a young prophet to anoint Jehu king of Israel (ix. 1); how he went to Damascus, told the sick king Benhadad that he would recover, and, at the same time, by foretelling the havoc that Benhadad's messenger Hazael would make of Israel, incited him to murder Benhadad and usurp his throne (viii. 7–15); how, in a time of peace between Israel and Syria, he prevented the outbreak of war by healing Naaman the Syrian general (v. 1–19), and, in a time of war, helped the king of Israel by his foreknowledge of the enemy's plans (vi. 12) and *moral* (vii. 1, 6), and by delivering into his hands a Syrian army smitten with supernatural blindness (vi. 13–23); how on his death-bed he predicted (or contrived by magic) three victories against Syria for Joash, king of Israel.

Some of these stories probably preserve memories of historical fact. The account of Jehu's rebellion seems to come from a trustworthy, perhaps contemporary, source; the evidence of the Moabite Stone gives support to the story of a campaign of Israel against Moab in the last days of the House of Omri; and a siege of Samaria of which no other record except 2 Kings vi. survives, may well have happened in the days when "the king of Syria oppressed Israel" (xiii. 22). There are indications, however, that these days did not begin before the accession of Jehu (*e.g.* x. 32); and if so, then, so far as they are historical, the stories in which Elisha aids kings of Israel against Syria must be taken to refer

to the dynasty of Jehu.

The historical person behind the Elisha stories was probably a prophetic supporter of the house of Jehu, who encouraged Israel in the darkest days of the Syrian wars. The precise nature of his religious ideas and of his connection, if any, with the historical person behind the Elijah stories must be left uncertain.

Elisha is mentioned in Ecclus. xlviii. 12–16, Luke iv. 27. For further information and literature *see* ELIJAH. (F. S. M.)

ELISHA BEN ABUYAH (*fl. c.* A.D. 100), a unique figure among the Palestinian Jews of his day, was born before the destruction of the Temple (A.D. 70). He refused to accept the current rabbinical views, though the Talmud cites his legal decisions. Most authorities believe that he was a Gnostic, but it is possible that he was simply a Sadducee, and thus an opponent not of Judaism but of Pharisaism. The efforts of his disciple, the famous Pharisee Meir, to reclaim his former master are among the most pathetic incidents in the Talmud. In later ages Elisha was regarded as the type of a heretic whose pride of intellect betrayed him into infidelity to law and morals.

ELIXIR, in alchemy, the medium which would effect the transmutation of base metals into gold; it probably had a wider meaning than "philosopher's stone." The same term, more fully *elixir vitae*, elixir of life, was given to the substance which would indefinitely prolong life; it was considered to be closely related to, or even identical with, the substance for transmuting metals. In pharmacy the word was formerly given to a strong extract or tincture.

ELIZABETH, SAINT (1207–1231), daughter of Andrew II., king of Hungary (d. 1235), was born in Pressburg. Married at the age of fourteen to Louis IV., landgrave of Thuringia, she devoted herself to religion and to works of charity. According to the legend, much celebrated in German art, Louis at first forbade her unbounded gifts to the poor. One day he saw his wife descending from the Wartburg with a heavy bundle of bread. He sternly bade her open it; she did so, and he saw nothing but a mass of red roses. The miracle converted him. On the death of Louis "the Saint" in 1227, Elizabeth was deprived of the regency by his brother, Henry Raspe IV. (d. 1247), on the pretext that she was wasting the estates by her alms. With her three infants she was driven from her home without even the barest necessities, but ultimately her maternal uncle, Egbert, bishop of Bamberg, offered her a house adjoining his palace. Through the intercession of some of the principal barons, the regency was again offered her, and her son Hermann was declared heir to the landgraviate. Renouncing all power, Elizabeth chose to live in seclusion at Marburg under the direction of her confessor, Conrad of Marburg, doing penance and ministering to the sick. She died at Marburg on Nov. 17, 1231, and was canonized by Gregory IX. in 1235.

BIBLIOGRAPHY.—Lives of St. Elizabeth were written by Theodoricus (Dietrich) of Apolda (b. 1228), Caesarius of Heisterbach (d. *c.* 1240), Conrad of Marburg and others (*see* Potthast, *Bibl. Hist. Med. Aev.* p. 1284). *See* also Montalembert, *L'Histoire de Élisabeth de Hongrie* (1836); A. Saubin, *S. Élisabeth de Hongrie* (1902); A. Huyskens, *Quellenstudien zur Gesch. der hl. Elisabeth* (Marburg, 1908); Wenck, *Die hl. Elisabeth* (Tübingen, 1908) and M. Maresch, *Elisabeth Landgräfin v. Thüringen* (2nd ed., 1921). The life of Elizabeth inspired Kingsley's poem "The Saint's Tragedy."

ELIZABETH [PETROVNA] (1709–1762), EMPRESS OF RUSSIA, the daughter of Peter the Great and Martha Skovronskaya, born at Kolomenskoye, near Moscow, on Dec. 18, 1709. From her earliest years she delighted every one by her extraordinary beauty and vivacity, and she developed a keen political and diplomatic sense in spite of the deficiencies of her early education. Various proposals for her marriage failed, so that on the death of her mother (May 1727) and the departure to Holstein of her sister Anne, her only remaining near relation, the princess found herself at the age of 18 practically her own mistress. So long as Menshikov remained in power, she was treated with liberality and distinction by the Government of Peter II., but the Dolgorukis, who supplanted Menshikov and hated the memory of Peter the Great, practically banished Peter's daughter from court. While still in her teens Elizabeth made a lover of Alexius Shubin, a sergeant in the Semenovsky Guards, and after his banishment to Siberia, minus his tongue, by order of the empress Anne, consoled herself with a young Cossack, Alexius Razumovski, whom she is said actually to have married. During the reign of her cousin Anne (1730–40), Elizabeth effaced herself as much as possible; but under the regency of Anna Leopoldovna the course of events drove her to overthrow the existing government. The French ambassador, La Chétardie, who was plotting to destroy the Austrian influence then dominant at the Russian court, seems to have urged her on, and lent her a small sum of money, but he took no part in the coup when it came. Elizabeth acted because she had reason to fear imprisonment in a convent for life. On the night of Dec. 6–7, 1741, she assembled her personal friends and members of her household, drove to the barracks of the Preobrazhensky Guards, enlisted their sympathies by a stirring speech, and led them to the Winter Palace. She seized the regent and her children in their beds, and summoned all the notables, civil and ecclesiastical, to her presence. Elizabeth had secured the ministers on her way to the Winter Palace, and the revolution was accomplished without further ado. Fortunately, Elizabeth Petrovna, with all her shortcomings, had inherited some of her father's genius for government. Her usually keen judgment and her diplomatic tact again and again recall Peter the Great. What in her sometimes seemed irresolution and procrastination, was, most often, a wise suspense of judgment.

After abolishing the cabinet council system in favour during the rule of the two Annes, and reconstituting the senate as it had been under Peter the Great,—with the chiefs of the departments of State, all of them now Russians again, as *ex-officio* members under the presidency of the sovereign—the first care of the new empress was to compose her quarrel with Sweden. On Jan. 23, 1743, direct negotiations between the two powers were opened at Åbo, and on Aug. 7, 1743, Sweden ceded to Russia all the southern part of Finland east of the river Kymmene, including the fortresses of Villmanstrand and Fredrikshamn. Much of this success in foreign policy was due to the new vice chancellor, Alexius Bestuzhev-Ryumin (*q.v.*). He represented the anti-Franco-Prussian portion of the council, and his object was to bring about an Anglo-Austro-Russian alliance which, at that time, was undoubtedly Russia's proper system. Hence the reiterated attempts of Frederick the Great and Louis XV. to get rid of Bestuzhev, which made the Russian court during the earlier years of Elizabeth's reign the centre of a tangle of intrigue (*see* BESTUZHEV-RYUMIN, ALEXIUS.) By the treaty of Aix-la-Chapelle (Oct. 18, 1748) Bestuzhev had extricated his country from the Swedish imbroglio; he had reconciled his imperial mistress with the courts of Vienna and London, her natural allies; enabled Russia to assert herself effectually in Poland, Turkey and Sweden, and isolated the king of Prussia by environing him with hostile alliances. All this would have been impossible but for the steady support of Elizabeth, who trusted him implicitly, despite the insinuations of the chancellor's innumerable enemies, most of whom were her personal friends.

The great event of Elizabeth's later years was the Seven Years' War. Elizabeth rightly regarded the treaty of Westminster (Jan. 16, 1756, whereby Great Britain and Prussia agreed to unite their forces to oppose the entry into, or the passage through, Germany of the troops of every foreign power) as utterly subversive of the previous conventions between Great Britain and Russia. Fear of the king of Prussia, who was "to be reduced within proper limits," so that "he might be no longer a danger to the empire," induced Elizabeth to accede to the treaty of Versailles, in other words the Franco-Austrian league against Prussia, and on May 17, 1757 the Russian army, 85,000 strong, advanced against Königsberg. Neither the serious illness of the empress, which began with a fainting-fit at Tsarskoe Selo (Sept. 19, 1757), nor the fall of Bestuzhev (Feb. 21, 1758), nor the cabals and intrigues of the various foreign powers at St. Petersburg, interfered with the progress of the war, and the crushing defeat of Kunersdorf (Aug. 12, 1759) at last brought Frederick to the verge of ruin. From the end of 1759 to the end of 1761, the unshakable firmness of the Russian empress was the one constraining political force which held together the heterogeneous, incessantly jarring elements of the anti-

Prussian combination.

On May 21, 1760, a fresh convention was signed between Russia and Austria, a secret clause of which, never communicated to the court of Versailles, guaranteed East Prussia to Russia, as an indemnity for war expenses. The failure of the campaign of 1760, so far as Russia and France were concerned, induced the court of Versailles to present (Jan. 22, 1761) to the court of St. Petersburg a despatch to the effect that the king of France desired peace. The Austrian ambassador, Esterhazy, presented a similar despatch. The Russian empress's reply was delivered on Feb. 12. Elizabeth declined any pacific overtures until the original object of the league had been accomplished. Simultaneously, Elizabeth proposed in a secret letter to Louis XV. a new treaty of closer alliance without the knowledge of Austria. Elizabeth's object seems to have been to reconcile France and Great Britain, in return for which service France was to throw all her forces into the German war. This project, which lacked neither ability nor audacity, foundered upon Louis XV.'s jealousy of Russian influence in eastern Europe and his fear of offending the Porte. It was finally arranged by the allies that their envoys at Paris should fix the date for a peace congress, and that, in the meantime, the war against Prussia should be vigorously prosecuted. Frederick acted on the defensive with consummate skill, but his situation had become desperate, when his difficulties were dispersed by the death of the Russian empress (Jan. 5, 1762), which he described in a letter to Prince Frederick of Brunswick as a great event.

See Robert Nisbet Bain, *The Daughter of Peter the Great* (1899); Sergyei Solovev, *History of Russia* (Rus.), vols. xx.–xxii. (St. Petersburg, 1857–77); *Politische Correspondenz Friedrichs des Grossen*, vols. i.–xxi. (1879, etc.); Colonel Masslowski, *Der siebenjährige Krieg nach russischer Darstellung* (1888–93); Kazinsierz Waliszewski, *La Dernière des Romanov* (1902).

ELIZABETH (1533–1603), queen of England and Ireland, born on Sunday, Sept. 7, 1533, and, like all the Tudors except Henry VII., at Greenwich palace, was the only surviving child of Henry VIII. by his second queen, Anne Boleyn. Charles V.'s ambassador, Chapuys, hardly deigned to mention the fact that the king's *amie* had given birth to a daughter, and both her parents were bitterly disappointed with her sex. She was, however, given precedence over Mary, her elder sister by 16 years, and Mary never forgave the infant's offence. Even this dubious advantage only lasted three years until her mother was beheaded, and "divorced." Elizabeth has been censured for having made no effort in later years to clear her mother's memory; but no vindication of Anne's character could have rehabilitated Elizabeth's legitimacy. Her mother was not "divorced" for her alleged adultery, because that crime was no ground for divorce by Roman or English canon law. The marriage was declared invalid *ab initio* either on the ground of Anne's precontract with Lord Percy or more probably on the ground of the affinity established between Henry and Anne by Henry's previous relations with Mary Boleyn.

Elizabeth thus lost the hereditary title to the throne. Nor was her legitimacy ever legally established; but after Jane Seymour's death, when Henry seemed likely to have no further issue, she was by act of parliament placed next in order of the succession after Edward and Mary and their issue; and this statutory arrangement was confirmed by the will which Henry VIII. was empowered by statute to make. Queen Catherine Parr introduced some humanity into Henry's household, and Edward and Elizabeth were well and happily educated together, principally at old Hatfield house. They were there when Henry's death called Edward VI. away to greater dignities, and Elizabeth was left in the care of Catherine Parr, who married in indecent haste Thomas, Lord Seymour, brother of the protector Somerset. This unprincipled adventurer, even before Catherine's death in September 1548, paid indelicate attentions to Elizabeth. Any attempt to marry her without the council's leave would have been treason on his part and would have deprived Elizabeth of her contingent right to the succession. Accordingly, when Seymour's other misbehaviour led to his arrest, his relations with Elizabeth were made the subject of a very trying investigation, which gave Elizabeth her first lessons in the feminine arts of self-defence. Although in later years Elizabeth seems to have cherished his memory, and certainly showed no love for his brother's children, at the time she only showed resentment at the indignities inflicted on herself.

For the rest of Edward's reign Elizabeth's life was less tempestuous. She hardly rivalled Lady Jane Grey as the ideal Puritan maiden, but she swam with the stream, and was regarded as a foil to her stubborn Catholic sister. She thus avoided the enmity and the still more dangerous favour of Northumberland; and some unknown history lies behind the duke's preference of the Lady Jane to Elizabeth as his son's wife and his own puppet for the throne. She thus escaped shipwreck in his crazy vessel, and rode by Mary's side in triumph into London on the failure of the plot. For a time she was safe enough; she would not renounce her Protestantism until Catholicism had been made the law of the land, but she followed Gardiner's advice to her father when he said it was better that he should make the law his will than try to make his will the law. As a presumptive ruler of England she was, like Cecil, and for that matter the future archbishop Parker also, too shrewd to commit herself to passive or active resistance to the law. Their position was well enough understood in those days; it was known that they were heretics at heart, and that when their turn came they would once more overthrow Catholicism and expect a similar submission from the Catholics.

It was not so much Elizabeth's religion as her nearness to the throne and the circumstances of her birth that endangered her life in Mary's reign. While Mary was popular Elizabeth was safe; but as soon as the Spanish marriage project had turned away English hearts Elizabeth inevitably became the centre of plots and the hope of the plotters. Had not Lady Jane still been alive to take off the edge of Mary's indignation and suspicion Elizabeth might have paid forfeit for Wyat's rebellion with her life instead of imprisonment. She may have had interviews with French agents who helped to foment the insurrection; but she was strong and wary enough to avoid Henry II.'s, as she had avoided Northumberland's, toils; for even in case of success she would have been the French king's puppet, placed on the throne, if at all, merely to keep it warm for Henry's prospective daughter-in-law, Mary Stuart. This did not make Mary Tudor any more friendly, and, although the story that Elizabeth favoured Courtenay and that Mary was jealous is a ridiculous fiction, the Spaniards cried loud and long for Elizabeth's execution. She was sent to the Tower in March 1554, but few Englishmen were fanatic enough to want a Tudor beheaded. The great nobles, the Howards, and Gardiner would not hear of such a proposal; and all the efforts of the court throughout Mary's reign failed to induce parliament to listen to the suggestion that Elizabeth should be deprived of her legal right to the succession. After two months in the Tower she was transferred to Sir Henry Bedingfield's charge at Woodstock, and at Christmas, when the realm had been reconciled to Rome and Mary was expecting issue, Elizabeth was once more received at court. In the autumn of 1555 she went down to Hatfield, where she spent most of the rest of Mary's reign, enjoying the lessons of Ascham and Baldassare Castiglione, and planting trees which still survive.

She had only to bide her time. The Protestant martyrs and Calais between them removed all the alternatives to an insular national English policy in church and in state; and no sovereign was better qualified to lead such a cause than the queen who ascended the throne amid universal rejoicings at Mary's death on Nov. 17, 1558. "Mere English" she boasted of being, and after Englishmen's recent experience there was no surer title to popular favour. No sovereign since Harold had been so purely English in blood; her nearest foreign ancestor was Catherine of France, the widow of Henry V., and no English king or queen was more superbly insular in character or in policy. She was the unmistakable child of the age so far as Englishmen shared in its characteristics, for with her English aims she combined some Italian methods and ideas. "An Englishman Italianate," ran the current jingle, "is a devil incarnate," and Elizabeth was well versed in Italian scholarship and statecraft. Italians, especially Bernardino Ochino, had given her religious instruction, and the Italians who rejected Catholicism usually adopted far more advanced forms of heresy than Lutheranism, Zwinglianism or even

Calvinism. Elizabeth herself patronized Giacomo Acontio, who thought dogma a "stratagema Satanae," and her last favourite, Essex, was accused of being the ringleader of "a damnable crew of atheists." A Spanish ambassador early in the reign thought that Elizabeth's own religion was equally negative, though she told him she agreed with nearly everything in the Augsburg Confession. She was probably not at liberty to say what she really thought, but she made up by saying a great many things which she did not mean. It is clear enough that, although, like her father, she was fond of ritual, she was absolutely devoid of the religious temperament, and that her ecclesiastical preferences were dictated by political considerations. She was sincere enough in her dislike of Roman jurisdiction and of Calvinism; a daughter of Anne Boleyn could have little affection for a system which made her a bastard, and all monarchs agreed at heart with James I.'s aphorism about "no bishop, no king." It was convenient, too, to profess Lutheran sympathies, for Lutheranism was now an established, monarchical and comparatively respectable religion, very different from the Calvinism against which monarchs directed the Counter-reformation from political motives. Lutheran dogma, however, had few adherents in England, though its political theory coincided with that of Anglicanism in the 16th century. The compromise that resulted from these conflicting forces suited Elizabeth very well; she had little dislike of Catholics who repudiated the papacy, but she was forced to rely mainly on Protestants, and had little respect for any form of ecclesiastical self-government. She valued uniformity in religion, not as a safeguard against heresy, but as a guarantee of the unity of the state. She respected the bishops only as supporters of her throne; and although the well-known letter beginning "Proud Prelate" is an 18th century forgery, it is hardly a travesty of Elizabeth's attitude.

The outlines of her foreign policy are sketched elsewhere (*see* ENGLISH HISTORY), and her courtships were diplomatic. Contemporary gossip, which was probably justified, said that she was debarred from matrimony by a physical defect; and her cry when she heard that Mary queen of Scots had given birth to a son is the most womanly thing recorded of Elizabeth. Her features were as handsome as Mary's, but she had little fascination, and in spite of her many suitors no man lost his head over Elizabeth as men did over Mary. She was far too masculine in mind and temperament, and her extravagant addiction to the outward trappings of femininity was probably due to the absence or atrophy of deeper feminine instincts. In the same way the impossibility of marriage made her all the freer with her flirtations, and she carried some of them to lengths that scandalized a public unconscious of Elizabeth's security. She had every reason to keep them in the dark, and to convince other courts that she could and would marry if the provocation were sufficient. She could not marry Philip II., but she held out hopes to more than one of his Austrian cousins whenever France or Mary Stuart seemed to threaten; and later she encouraged two French princes when Philip had lost patience with Elizabeth and made Mary Stuart his protégée. Her other suitors were less important, except Leicester, who appealed to the least intellectual side of Elizabeth and was always a cause of distraction in her policy and her ministers.

Elizabeth was terribly handicapped by having no heirs of her body and no obvious English successor. She could not afford to recognize Mary's claim, for that would have been to alienate the Protestants, double the number of Catholics, and, in her own phrase, to spread a winding-sheet before her eyes; for all would have turned to the rising sun. Mary was dangerous enough as it was, and no one would willingly make his rival his heir. Elizabeth could hardly be expected to go out of her way and ask parliament to repeal its own acts for Mary's sake; probably it would have refused. Nor was it personal enmity on Elizabeth's part that brought Mary to the block. Parliament had long been ferociously demanding Mary's execution, not because she was guilty but because she was dangerous to the public peace. She alone could have given the Spanish Armada any real chance of success; and as the prospect of invasion loomed larger on the horizon, fiercer grew the popular determination to remove the only possible centre of a domestic rising, without which the external attack was bound to be a failure. Elizabeth resisted the demand, not from compassion or qualms of conscience, but because she dreaded the responsibility for Mary's death. She wished Paulet would manage the business on his own account, and when at last her signature was extorted she made a scapegoat of her secretary Davison who had the warrant executed.

The other great difficulty, apart from the succession, with which Elizabeth had to deal arose from the exuberant aggressiveness of England, which she could not, and perhaps did not want to, repress. Religion was not really the cause of her external dangers, for the time had passed for crusades, and no foreign power seriously contemplated an armed invasion of England for religion's sake. But no state could long tolerate the affronts which English seamen offered Spain. The common view that the British Empire has been won by purely defensive action is not tenable, and from the beginning of her reign Englishmen had taken the offensive, partly from religious but also from other motives. They were determined to break up the Spanish monopoly in the New World, and in the pursuit of this endeavour they were led to challenge Spain in the old. For nearly 30 years Philip put up with the capture of his treasure-ships, the raiding of his colonies and the open assistance rendered to his rebels. Only when he had reached the conclusion that his power would never be secure in the Netherlands or the New World until England was conquered, did he despatch the Spanish Armada. Elizabeth delayed the breach as long as she could, probably because she knew that war meant taxation, the most prolific parent of revolt.

With the defeat of the Spanish Armada Elizabeth's work was done, and during the last 15 years of her reign she got more out of touch with her people. That period was one of gradual transition to the conditions of Stuart times; during it practically every claim was put forward that was made under the first two Stuarts either on behalf of parliament or the prerogative, and Elizabeth's attitude towards the Puritans was hardly distinguishable from James I.'s. But her past was in her favour, and so were her sex and her Tudor tact, which checked the growth of discontent and made Essex's rebellion a ridiculous fiasco. He was the last and the most wilful but perhaps the best of her favourites, and his tragic fate deepened the gloom of her closing years. She was desolate in old age after the deaths of Leicester, Walsingham, Burghley and Essex, and Elizabeth died, the last of her line, on March 24, 1603.

Bishop Creighton's *Queen Elizabeth* (1896) is the best biography; there are others by E. S. Beesly, *Twelve English Statesmen* (1892); Lucy Aikin, *Memoirs of the Court of Queen Elizabeth* (1818); and T. Wright, *Queen Elizabeth and her Times* (1838). *See* also A. Jessopp's article in the *Dict. Nat. Biog.*; Rowe, *Cal. of State Papers, relative to English affairs*, vol. 1, *Elizabeth, 1558–71* (1917); State Papers, *Cal. of S.P., Foreign Ser. of the reign of Elizabeth*, vol. xvii. (1913); and G. Lytton Strachey, *Elizabeth and Essex; a tragic history* (1928).

ELIZABETH [AMELIE EUGENIE] (1837–1898), consort of Francis Joseph, emperor of Austria and king of Hungary, was the daughter of Duke Maximilian Joseph of Bavaria and Louisa Wilhelmina, daughter of Maximilian I. of Bavaria, and was born on Dec. 24, 1837 at the castle of Possenhofen on Lake Starnberg. She inherited the quick intelligence and artistic taste displayed in general by members of the Wittelsbach royal house, and her education was the reverse of conventional. She accompanied her eccentric father on his hunting expeditions, becoming an expert rider and climber, visiting the peasants in their huts and sharing in rustic pleasures. The emperor of Austria, Francis Joseph, met the Bavarian ducal family at Ischl in Aug. 1853, and immediately fell in love with Elizabeth, then a girl of 16, and reported to be the most beautiful princess in Europe. The marriage took place in Vienna on April 24, 1854. In the early days of her married life she frequently came into collision with Viennese prejudice. Her attempts to modify court etiquette, and her extreme fondness for horsemanship and frequent visits to the imperial riding school, scandalized Austrian society, while her predilection for Hungary and for everything Hungarian offended German sentiment. There is no doubt that her influence helped the establishment of the *Ausgleich* with Hungary, but outside

Hungarian affairs the empress took small part in politics. She first visited Hungary in 1857, and ten years later was crowned queen. Her popularity with the Hungarians remained unchanged throughout her life; and the castle of Gödöllö, presented as a coronation gift, was one of her favourite residences. Elizabeth was one of the most charitable of royal ladies, and her popularity with her Austrian subjects was more than restored by her assiduous care for the wounded in the campaign of 1866. Besides her public benefactions she constantly exercised personal and private charity. Her eldest daughter died in infancy; Gisela (b. 1856) married the Prince Leopold of Bavaria; and her youngest daughter Marie Valerie (b. 1868) married the Archduke Franz Salvator. The tragic death of her only son, the crown prince Rudolph, in 1889, was a shock from which she never really recovered. She was also deeply affected by the suicide of her cousin Louis II. of Bavaria, and again by the fate of her sister Sophia, duchess of Alençon, who perished in the fire of the Paris charity bazaar in 1897. The empress had shown signs of lung disease in 1861, when she spent some months in Madeira; but she was able to resume her outdoor sports, and for some years before 1882, when she had to give up riding, was a frequent visitor on English and Irish hunting fields. In her later years her dislike of publicity increased. Much of her time was spent in travel or at the Achilleion, the palace she had built in the Greek style in Corfu. She was walking from her hotel at Geneva to the steamer when she was stabbed by the anarchist Luigi Luccheni, on Sept. 10, 1898, and died of the wound within a few hours. This aimless crime lengthened the list of misfortunes of the Austrian house, and aroused intense indignation throughout Europe.

See A. de Burgh, *Elizabeth, Empress of Austria, a Memoir* (London, 1898); E. Friedmann and J. Paves, *Kaiserin Elisabeth* (Berlin, 1898); and the anonymous *Martyrdom of an Empress* (1899), containing a quantity of court gossip.

ELIZABETH, QUEEN OF RUMANIA (1843–1916), best known by her pen-name of CARMEN SYLVA, was born on Dec. 29, 1843, the daughter of Prince Hermann of Neuwied, and married Prince (afterwards King) Charles of Rumania in 1869. The only daughter of the marriage died in 1874. She took a keen interest in the cultural development of her adopted country, especially in Rumanian poetry and folklore, and collected and edited many Rumanian legends. Much of her literary work was done in collaboration with Mite Kremnitz, her lady-in-waiting. She wrote easily in English, French, German and Rumanian. Her more important works were translated into many languages. Among them may be mentioned *Pensées d'une Reine* (1882), and, with Alma Strettell, *The Bard of the Dimbovitza* (1891), a fine English version of Hélène Vacarescu's collection of Rumanian folksongs. "Carmen Sylva" died on March 2, 1916.

See her own *Reminiscences* (1911); also M. Kremnitz, *Carmen Sylva—eine Biographie* (Leipzig, 1903); and, for a full bibliography, G. Bengescu, *Carmen Sylva—bibliographie et extraits de ses oeuvres* (1904).

ELIZABETH (1596–1662), consort of Frederick V., elector palatine and titular king of Bohemia, was the eldest daughter of James I. of Great Britain and of Anne of Denmark, and was born at Falkland Castle, Fifeshire, in Aug. 1596. She was entrusted to the care of the earl of Linlithgow, and after the departure of the royal family to England, to the countess of Kildare, subsequently residing with Lord and Lady Harington at Combe Abbey in Warwickshire. In Nov. 1605 the Gunpowder Plot conspirators formed a plan to seize her person and proclaim her queen after the explosion, in consequence of which she was removed by Lord Harington to Coventry. In 1608 she appeared at court, where her beauty soon attracted admiration and became the theme of the poets, her suitors including the dauphin, Maurice, prince of Orange, Gustavus Adolphus, Philip III. of Spain and Frederick V., the elector palatine. A marriage with the elector palatine was finally arranged, in spite of the queen's opposition, in order to strengthen the alliance with the Protestant powers in Germany; it took place on Feb. 14, 1613, midst great rejoicing and festivities, described in Nichols's *Progresses of James I.* Among the many poems written in commemoration of the marriage is the *Epithalamion* by John Donne. The prince and princess entered Heidelberg on June 17. On Aug. 26, 1618, Frederick, as a leading Protestant prince, was chosen king by the Bohemians, who deposed the emperor Ferdinand, then archduke of Styria. Elizabeth accompanied Frederick to Prague in Oct. 1619, and was crowned on Nov. 7. Here her unrestrainable high spirits and levity gave great offence to the citizens. But in misfortune she showed great courage and fortitude. She left Prague on Nov. 8, 1620, after the fatal battle of the White Hill, for Küstrin, travelling thence to Berlin and Wolfenbüttel, finally with Frederick taking refuge at The Hague with Prince Maurice of Orange.

It was not until the peace of Westphalia in 1648 that her son, Charles Louis, regained a portion of his dominions, the Rhenish Palatinate. Meanwhile, the payment of Elizabeth's English annuity of £12,000 ceased after the outbreak of the troubles with the parliament; the execution of Charles I. in 1649 put an end to all hopes from that quarter; and the pension allowed her by the house of Orange ceased in 1650. Her children abandoned her, and her son Charles Louis refused her a home in his restored electorate. Nor did Charles II. at his restoration show any desire to receive her in England. Parliament voted her £20,000 in 1660 for the payment of her debts, but Elizabeth did not receive the money, and on May 10, 1661, she left The Hague for England, where Charles, who had opposed her coming, ultimately granted her a pension. She died on Feb. 13, 1662, and was buried in Westminster Abbey. Her beauty, grace and vivacity exercised a great charm over her contemporaries, who were also moved by her misfortunes incurred in the Protestant cause. As the ancestress of the Protestant Hanoverian dynasty, she became a prominent figure in English history. She had 13 children—Frederick Henry, drowned at sea in 1629; Charles Louis, elector palatine, whose daughter married Philip, duke of Orleans, and became the ancestress of the elder and Roman Catholic branch of the royal family of England; Elizabeth, abbess and friend of Descartes; Prince Rupert and Prince Maurice, who died unmarried; Louisa, abbess; Edward, who married Anne de Gonzaga, "princesse palatine," and had children; Henrietta Maria, who married Count Sigismund Ragotzki, but died childless; Philip and Charlotte, who died childless; Sophia, who married Ernest Augustus, elector of Hanover, and was mother of George I. of England; and two others who died young.

BIBLIOGRAPHY.—*See* the article in *Dict. of Nat. Biography* and authorities there collected; *Five Stuart Princesses*, ed. by R. S. Rait (1902); A. Wendland, *Briefe der Elizabeth Stuart . . . an . . . den Kurfürsten Carl Ludwig von der Pfalz* (Bibliothek des literarischen Vereins, 228, Stuttgart, 1902); J. O. Opel, "Elizabeth Stuart," in Sybel's *Historische Zeitschrift*, xxiii. 289; *Thomason Tracts* (Brit. Mus.), E., 138 (14), 122 (12), 118 (40), 119 (18). Important material regarding the princess exists in the MSS. of the earl of Craven, at Combe Abbey.

ELIZABETH (1635–1650), English princess, second daughter of Charles I., was born on Dec. 28, 1635, at St. James's Palace. On the outbreak of the Civil War and the departure of the king from London, while the two elder princes accompanied their father, the princess and the infant duke of Gloucester were left under the care of the parliament. In July 1644 the royal children were sent to Sir John Danvers at Chelsea, and in 1645 to the earl and countess of Northumberland. After the final defeat of the king they were joined in 1646 by James, and during 1647 paid several visits to the king at Caversham, near Reading, and Hampton Court, but were again separated by Charles's imprisonment at Carisbrooke castle. On April 21, 1648, James was persuaded to escape by Elizabeth, who declared that were she a boy she would not long remain in confinement. The last sad meeting between Charles and his two children, at which the princess was overcome with grief, and of which she wrote a short and touching account, took place on Jan. 29, 1649, the day before his execution. In June she was sent to the earl and countess of Leicester at Penshurst, but in 1650, upon the landing of Charles II. in Scotland, the parliament ordered the royal children to be taken for security to Carisbrooke castle. The princess fell ill, and died of fever on Sept. 8. She was buried in St. Thomas's church at Newport, Isle

of Wight, where the initials "E.S." alone marked her grave till 1856, when a monument was erected to her memory by Queen Victoria. Several books were dedicated to the princess, including the translation of the *Electra* of Sophocles by Christopher Wase in 1649. Her mild nature and gentleness towards her father's enemies gained her the name of "Temperance."

See M. A. E. Green, *Lives of the Princesses of England* (1855), vol. vi.

ÉLIZABETH (Élisabeth Philippine Marie Hélène of France) (1764–1794), commonly called MADAME ÉLIZABETH, daughter of Louis the Dauphin and Marie Josephine of Saxony, and sister of Louis XVI., was born at Versailles on May 3, 1764. At the outset of the revolution she foresaw the gravity of events, and refused to leave the king, whom she accompanied in his flight on June 20, 1792, and with whom she was arrested at Varennes. She was present at the Legislative Assembly when Louis was suspended, and was imprisoned in the Temple with the royal family. By the execution of the king and the removal of Marie Antoinette to the Conciergerie, Madame Élizabeth was deprived of her companions in the Temple prison, and on May 9, 1794 she was herself transferred to the Conciergerie, and brought before the revolutionary tribunal. She was condemned to death, and executed on May 10, 1794.

The *Mémoires de Madame Élisabeth* (Paris, 1858), by F. de Barghon and Fort-Rion, are of doubtful authenticity; and the collection of letters and documents published in 1865 by F. Feuillet de Conches must be used with caution. *See* le Comte A. F. C. Ferrand, *Éloge historique de Madame Élisabeth* (1814, containing 94 letters; 2nd ed., 1861, containing additional letters, but correspondence mutilated); Du Fresne de Beaucourt, *Étude sur Madame Élisabeth* (Paris, 1864); A. de Beauchesne, *Vie de Madame Élisabeth* (1869); La comtesse d'Armaillé, *Madame Élisabeth* (Paris, 1886); Madame d'Arvor, *Madame Élisabeth* (Paris, 1898); and Hon. Mrs. Maxwell-Scott, *Madame Elisabeth of France* (1908).

ELIZABETH, a city of New Jersey, U.S.A., the county seat of Union county; on Newark bay, opposite Staten island, with which it is connected by the Goethals bridge (opened on June 20, 1928). It is on the Lincoln highway, and is served by the Baltimore and Ohio, the Central of New Jersey, the Lehigh Valley and the Pennsylvania railways. The population was 95,783 in 1920 (29·5% foreign-born white) and was estimated locally at 120,000 in 1928. Elizabeth combines the character of a residential suburb of New York with that of an important independent industrial centre. It has a vast plant (with 8,000 workers) making Singer sewing-machines, an oil refinery covering 800ac., shipbuilding yards, automobile factories and numerous other manufacturing industries. The total factory output in 1925 was $116,245,464. Elizabethport, the city's harbour on Staten island sound, is a receiving and distributing point for coal from the Pennsylvania anthracite fields. The assessed valuation of property for 1928 was $156,506,487. Elizabeth was settled in 1665 by colonists from Long island, for whom the land had been bought from the Indians and a grant obtained from the agent of the duke of York. But about the same time the duke conveyed the entire province to Lord Berkeley and Sir George Carteret, and the conflicting grants gave rise to a long controversy. The town was named after the wife of Sir George, and was at first called Elizabethtown. It was the capital of the province from 1665 to 1686, and until 1790 the legislature sat here occasionally. The first sessions of the College of New Jersey (now Princeton university) were held (1747) in the home of the Rev. Jonathan Dickinson (1688–1747). In Dec. 1776, and twice in June 1780, the British entered the town and made it a base of operations, but on each occasion they were soon driven out. Elizabeth became a free town and borough in 1739; the borough charter was confirmed in 1789 and repealed in 1790; and a city charter was received in 1855. Among the historic buildings still standing are Liberty hall (1772), the mansion of William Livingston, first governor of the State; Boxwood hall, the home of Elias Boudinot; the brick mansion (1742) of Jonathan Belcher (1681–1757), governor of the province from 1747–1757; the home of General Winfield Scott; and the First Presbyterian church (present building erected 1784–86), where in 1668 the first general assembly of the province convened. Several smaller structures (including Hetfield house, built in 1667) date from the 17th century.

ELIZABETHAN STYLE, in architecture, a term loosely applied to the early Renaissance work in England up to the end of the 16th century. The term Tudor Period (*q.v.*) is generally limited to the earlier Elizabethan work, in which Gothic elements are still dominant; the Jacobean style (*q.v.*) is used of the later portion of the period, in which Renaissance ideas had finally conquered. These three terms are overlapping and there is much variety of usage in the meanings given to them by different authorities. In general, the Elizabethan style is that which resulted from the impingement upon the vivid perpendicular Gothic tradition, first of Italian Renaissance artists, such as Pietro Torregiano, who designed the tomb of Henry VII., and later of a great number of Flemish craftsmen who settled in England. Thus, such buildings as Hampton Court palace, Sutton place in Surrey, Hatfield House and Audley End, varying as they do from the Gothic of Hampton Court to the Renaissance of Hatfield, are all spoken of as in the Elizabethan style.

ELIZABETH CITY, a city of North Carolina, U.S.A., 46m. S. of Norfolk, at the head of navigation on the Pasquotank river; a port of entry and the county seat of Pasquotank county. It is on Federal highway 17, and is served by the Norfolk Southern railroad and by steamers through the Dismal Swamp and the Albemarle and Chesapeake canals. The population was 8,925 in 1920 (39% negroes) and was estimated locally at 12,000 in 1928. It is the commercial centre of the north-eastern part of the State; the shipping point for quantities of market-garden produce; a rendezvous for hunters and fishermen; the seat of a State normal school for negroes; and has shipyards, hosiery and cotton mills, and various other manufacturing industries. The city was founded and incorporated in 1793. It has a council-manager form of government. On Roanoke island, 45m. S.E., the followers of Sir Walter Raleigh landed in 1584 and Virginia Dare was born in 1587; and near by is Kitty Hawk, where the Wright brothers in 1903 made their first successful flight. Just outside the city, on the banks of Halls Creek, is the spot where the first general assembly of Virginia met on Feb. 6, 1665.

ELIZABETHTON, a rapidly growing city of north-eastern Tennessee, U.S.A., at the junction of the Doe and Watauga rivers, 1,575ft. above sea-level; the county seat of Carter county. It is served by the East Tennessee and Western North Carolina and the Southern railways. The population was 2,749 in 1920 (98% native white) and was estimated locally at over 10,000 in 1928. It is in one of the most beautiful spots of the southern Appalachian mountains, in a region rich in minerals, timber, fertile soil and water power. Hydro-electric power is available from a plant on the Watauga river. The city has various manufacturing industries, including two large plants making artificial silk, which when completed will employ 30,000 workers. It is one of the oldest settlements of the region, and is rich in historic associations. Under a giant sycamore still standing on the Doe was held (by Gen. Andrew Jackson) the first court in what is now Tennessee. At Sycamore Shoals, Revolutionary soldiers met for drill, and from here marched to the battle of King's Mountain. There is an iron furnace that was used in Revolutionary days, and on the banks of the Watauga is the last home of President Johnson. Elizabethton was chartered as a city in 1905. It has a commission-manager form of government.

ELIZABETH TUNNEL, 60 m. N. of Los Angeles, Calif., is the longest of the 164 Los Angeles aqueduct tunnels, being 5·1 m. in length. It was constructed through the Coast Range mountains, a region of great topographic difficulty, at a cost of $70.20 per ft., requiring five years to bring it to completion (Feb. 28, 1911). Horseshoe in shape, it was constructed from two headings, 20 m. from a railroad base, is lined throughout with concrete, and measures 9 ft. 6 in. in width and 10 ft. 10 in. in height.

ELK or MOOSE (*Alces machlis*), the largest of the deer tribe, inhabiting the subarctic forests of both the New and the Old Worlds, though the American form (to which the name "Moose" is properly restricted) is sometimes separated as *A. americana*. The distinguishing features of the elk are the huge palmate, projecting antlers, the long legs, the long fleshy muzzle, and the short

neck. Despite its ungainly appearance, the moose can gallop at a considerable speed. It feeds on leaves and shoots of the willow and birch. During the winter the American race assemble in small herds, composed of a male and several females, and, by trampling the snow, form an open space known as a "moose-yard," in which they can move about with some freedom. Generally very shy, in the breeding season, which is in the autumn, the males become bold and fierce and fight savagely with antlers and hoofs. "Moose-calling" is a favourite sport in Canada. In most parts of Europe and America the elk is now protected by law. In North America the name elk is commonly applied to the Wapiti (*Cervus canadensis*). For "Irish-Elk," *see* FALLOW-DEER.

ELKHART, a city of Elkhart county, Indiana, U.S.A., at the confluence of the St. Joseph and the Elkhart rivers, 100m. E. of Chicago. It is on Federal highways 20 and 112; has an airport; and is served by the Big Four and the New York Central railways. Pop. 24,277 in 1920 (92·4% native white), and was estimated locally at 40,000 in 1928. The city is pleasantly situated at an altitude of 757ft., and within 30 miles there are about 100 lakes. A super-power plant eight miles west has a capacity of 300,000 h.p. Elkhart is a division point on the main line of the New York Central, which has large shops and classification yards here. The output of the factories of all kinds in 1925 was valued at $28,871,728. Chief among the manufactures are band instruments (to a value of $7,500,000 per year), automobiles, railway and steamship supplies, iron, bridges, paper and sheet-metal products. The assessed valuation of property in 1927 was $44,968,440. Elkhart was settled about 1834, and chartered in 1875.

ELKINGTON, GEORGE RICHARDS (1801–1865), founder of the electro-plating industry in England, was born in Birmingham on Oct. 17, 1801, the son of a spectacle manufacturer. Apprenticed to his uncles, silver platers in Birmingham, he became, on their death, sole proprietor of the business, but subsequently took his cousin, Henry Elkington, into partnership. The Elkingtons had already taken out certain patents for the application of electricity to metals when, in 1840, John Wright, a Birmingham surgeon, discovered the properties of a solution of cyanide of silver in cyanide of potassium for electro-plating purposes. The Elkingtons purchased and patented Wright's process, subsequently acquiring the rights of other processes and improvements. George Richards Elkington died on Sept. 22, 1865, and Henry Elkington on Oct. 26, 1852.

ELKINS, a city of West Virginia, U.S.A., in the mountainous eastern part of the state; the county seat of Randolph county. It is served by the Baltimore and Ohio and the Western Maryland railways. The population was 9,338 in 1928 (93% native white). It is in a lumbering and coal-mining region; has various manufacturing industries; and is the seat of Davis and Elkins college (Presbyterian), founded in 1903 by Senators Henry G. Davis and Stephen B. Elkins, who in 1889 had founded the town. Elkins was chartered as a city in 1889.

ELLA or **AELLA,** the name of three Anglo-Saxon kings.

ELLA (d. *c.* 514), king of the South Saxons and founder of the kingdom of Sussex, was a Saxon ealdorman, who landed near Arundel in Sussex with his three sons in 477. Defeating the Britons, Ella and his followers established themselves along the south coast. In 491, strengthened by the arrival of fresh bands of immigrants, they captured the Roman city of Anderida and "slew all that were therein." Ella, who is reckoned as the first Bretwalda, then became king of the South Saxons, and, when he died about 514, he was succeeded by his son Cissa.

ELLA (d. 588), king of the Deirans, the son of Iffa, became the first king of Deira when, in 559, the Deirans separated themselves from the kingdom of Bernicia. When Ella died in 588 Deira was conquered by Bernicia. One of his sons was Edwin, afterwards king of the Northumbrians.

ELLA (d. 867), king of the Northumbrians, became king about 862 on the deposition of Osbert, although he was not of royal birth. Afterwards he joined Osbert in an attack on the Danes, who had invaded Northumbria, and drove them into York. The Danes, however, defeated the Northumbrians, and both Ella and Osbert were slain.

See *The Anglo-Saxon Chronicle*, ed. by C. Plummer (1892–99); Bede, *Historiae ecclesiasticae*, ed. by C. Plummer (Oxford, 1896); Henry of Huntingdon, *Historia Anglorum*, ed. by T. Arnold, Rolls Series (1879); Asser, *De rebus gestis Aelfredi*, ed. by W. H. Stevenson (1904); J. R. Green, *The Making of England* (1897); and the *Dictionary of National Biography*, vol. i. (1895).

ELLAND, an urban district in Yorkshire, England, on the river Calder, 2½ m. S. of Halifax by the L.M.S. railway. Pop. (1921), 10,552. It is situated on the south bank of the Calder, on gently sloping ground, which rises steeply away from the town to an altitude of 800 feet. A col in the high land is used by a road which communicates with Huddersfield, Brighouse and Oldham. Communication is also effected with Halifax by road along the valley bottom and by the Calder canal. The Church of St. Mary is Decorated and Perpendicular.

Cotton mills, woollen factories, ironworks, flagstone quarries at Elland Edge, and fireclay works employ the industrial population.

ELLENBOROUGH, EDWARD LAW, 1ST BARON (1750–1818), English judge, was born on Nov. 16, 1750, at Great Salkeld, Cumberland, where his father, afterwards bishop of Carlisle, was rector. He was educated at the Charterhouse and at Peterhouse, Cambridge, and afterwards was entered at Lincoln's Inn. He spent five years as a special pleader and was called to the bar in 1780. He was unexpectedly chosen to lead the defence of Warren Hastings before the House of Lords, in 1787, Erskine having declined for political reasons. This most famous trial in English history lasted until 1795, when a verdict of acquittal was given. Law did not open the defence till 1792. At the end of it he was second only to Erskine at the bar. During the French Revolution he joined Pitt, was made attorney-general in 1801, and chief justice of the King's Bench with the title of Lord Ellenborough in 1802. He was the judge in the famous case of Ashford v. Thornton, the last case of Appeal of Battle in England. In 1806, on the formation of Lord Grenville's ministry "of all the talents," Lord Ellenborough declined the offer of the great seal, but accepted a seat in the cabinet while retaining the chief justiceship. This action was much criticized and, though not without precedent, was open to such obvious objections on constitutional grounds that the experiment has not been repeated. As a judge his decisions displayed profound legal knowledge, and in mercantile law especially were reckoned of high authority. He was harsh and overbearing to counsel, and in political trials showed an unmistakable bias. In the trial of William Hone (*q.v.*) for blasphemy in 1817, Ellenborough directed the jury to find a verdict of guilty, and their acquittal of the prisoner is generally said to have hastened his death. He resigned his judicial office in Nov. 1818, and died the following month. He had married in 1789 Miss Towry, and had a large family.

ELLENBOROUGH, EDWARD LAW, EARL OF (1790–1871), the eldest son of the 1st Lord Ellenborough, was born on Sept. 8, 1790. He was educated at Eton and St. John's College, Cambridge. He represented the subsequently disfranchised borough of St. Michael's Cornwall, in the House of Commons, until the death of his father in 1818 gave him a seat in the House of Lords. He was twice married; his only child died young; his second wife was divorced by act of parliament in 1830. Ellenborough was lord privy seal (1828) and member of the board of control (1828–30). He had just returned to the board of control in 1841 when he was appointed by the court of directors of the East India Company to succeed Lord Auckland as governor-general of India.

India.—Ellenborough went to India in order "to restore peace to Asia," but the whole term of his office was occupied in war. On his arrival he was greeted by news of the massacre of Kabul, and the sieges of Ghazni and Jalalabad, while the sepoys of Madras were on the verge of open mutiny. In his proclamation of March 15, 1842, as in his memorandum for the queen dated the 18th, he stated the duty of first inflicting some signal and decisive blow on the Afghans, and then leaving them to govern themselves under the sovereign of their own choice. Unhappily, when he left his council for upper India, and learned the trifling failure of General England, he instructed Pollock and Nott, who were

advancing triumphantly with their avenging columns to rescue the British captives, to fall back. The army proved true to the governor-general's earlier proclamation rather than to his later fears; the hostages were rescued, the scene of Sir Alexander Burnes's murder in the heart of Kabul was burned down. Dost Mahommed was quietly dismissed from a prison in Calcutta to the throne in the Bala Hissar, and Ellenborough presided over the painting of the elephants for an unprecedented military spectacle at Ferozepur, on the south bank of the Sutlej. The farce of the recovery of the sandalwood gates of the Hindu temple of Somnath from the Afghans followed. The gates, conveyed to Agra in a triumphal car, were found to be a fraudulent imitation. The Somnath proclamation made Ellenborough ridiculous.

Hardly had Ellenborough issued his medal with the legend "Pax Asiae Restituta" when he was at war with the amirs of Sind. The tributary amirs had on the whole been faithful, for Major (afterwards Sir James) Outram controlled them. But he had reported the opposition of a few, and Ellenborough ordered an inquiry. His instructions were admirable, in equity as well as energy, and if Outram had been left to carry them out all would have been well. But the duty was entrusted to Sir Charles Napier, with full political as well as military powers. Mir Ali Morad intrigued with both sides; he betrayed the amirs on the one hand, while he deluded Napier to their destruction on the other. Ellenborough was led on till events were beyond his control, and his own just and merciful instructions were forgotten. Napier admitted that the seizure of Sind was an "advantageous, useful and humane piece of rascality." The battles of Meeanee and Hyderabad followed; and the Indus became a British river from Karachi to Multan.

On the north the disordered kingdom of the Sikhs was threatening the frontier. In Gwalior to the south, the feudatory Mahratta State, there were a large mutinous army, a Ranee only 12 years of age, an adopted chief of eight, and factions in the council of ministers. These conditions brought Gwalior to the verge of civil war. Ellenborough reviewed the danger in the minute of Nov. 1, 1845, and told Sir Hugh Gough to advance. Further treachery and military licence rendered the battles of Maharajpur and Punniar, fought on the same day, inevitable though they were, a surprise to the combatants. The treaty that followed was merciful and wise. The pacification of Gwalior also had its effect beyond the Sutlej, where anarchy was restrained for yet another year, and the work of civilization was left to Ellenborough's two successors. But by this time the patience of the directors was exhausted. They had no control over Ellenborough's policy; his despatches to them were haughty and disrespectful; and in June 1844 they recalled him.

England.—On his return to England Ellenborough was created an earl and received the thanks of parliament; but his administration was attacked in parliament, though it was successfully vindicated by Peel and Wellington. When Peel's cabinet was reconstituted in 1846 Ellenborough became first lord of the admiralty. In 1858 he took office under Lord Derby as president of the board of control, for the fourth time. There he drafted the new scheme for the government of India which the mutiny had rendered necessary. But he wrote a caustic despatch censuring Lord Canning for the Oudh proclamation, and allowed it to be published in *The Times* without consulting his colleagues, who disavowed his action. Votes of censure were announced in both Houses; and, to save the cabinet, Ellenborough resigned.

But for this act of rashness he might have enjoyed the task of carrying into effect the home constitution for the government of India which he sketched in his evidence before the select committee of the House of Commons on Indian territories on June 8, 1852.

Paying off his old score against the East India Company, he then advocated the abolition of the court of directors as a governing body, the opening of the civil service to the army, the transference of the government to the Crown, and the appointment of a council to advise the minister who should take the place of the president of the board of control. These suggestions of 1852 were carried out by his successor Lord Stanley, afterwards earl of Derby, in 1858, so closely even in details, that Ellenborough must be pronounced the author, for good or evil, of the home constitution of the government of India. Ellenborough never held office again. He died at his seat, Southam House, near Cheltenham, on Dec. 22, 1871, when the barony reverted to his nephew Charles Edmund Law (1820–1890), the earldom becoming extinct.

ELLESMERE, FRANCIS EGERTON, 1st Earl of (1800–1857), born in London on Jan. 1, 1800, was the second son of the 1st duke of Sutherland. As Lord Francis Leveson Gower he sat in parliament for various constituencies. He took the name of Egerton in 1833, and in 1846 was elevated to the peerage as earl of Ellesmere and Viscount Brackley. Appointed a lord of the treasury in 1827, he held the post of chief secretary for Ireland from 1828 till July 1830, when he became secretary-at-war for a short time.

Ellesmere translated Goethe's *Faust,* and published several works in prose and verse. He was a munificent and yet discriminating patron of artists. To the splendid collection of pictures which he inherited from his great-uncle, the 3rd duke of Bridgewater, he made numerous additions, and he built a gallery to which the public were allowed free access. Lord Ellesmere served as president of the Royal Geographical Society and as president of the Royal Asiatic Society, and he was a trustee of the National Gallery. He died on Feb. 18, 1857.

ELLESMERE, LORD CHANCELLOR: *see* Brackley, Thomas Egerton, Viscount.

ELLESMERE, urban district, Shropshire, England, situated near the north-west border of the county in a region of indeterminate drainage between the river systems of the Dee and Severn. Pop. (1921) 1,832. It lies on the west shore of the mere—a small lake of glacial origin—from which it takes its name. In the neighbourhood are other sheets of water, as Blake Mere, Cole Mere and Newton Mere. The manor of Ellesmere was granted by William I. to Roger, earl of Shrewsbury. The castle, of which nothing but a mound remains, was given by King John to Llewellyn. Position on the Welsh border ensured importance, and Ellesmere was granted all the free customs of Breteuil. The market granted to Llewellyn was discontinued in the 16th century, when the population of the town was severely reduced by the plague. Now disused, the Ellesmere canal, one of Telford's works, connects the Severn with the Mersey, crossing the Vale of Llangollen, in Denbighshire, by an immense aqueduct. The church of St. Mary contains some Norman work. Ellesmere is the centre of a dairy farming district, and has fairs and markets. It forms part of the Oswestry parliamentary division of Shropshire.

ELLICE (LAGOON) ISLANDS, an archipelago of the Pacific ocean, lying between 5° and 11° S. and about 178° E., nearly midway between Fiji and Gilbert. It was annexed by Britain in 1892, and has been since Jan. 1916 part of the Gilbert and Ellice Isles colony. It comprises a large number of low coral islands and atolls, in nine clusters extending over a distance of about 400 m. from north-west to south-east. Their total area is 14 sq.m. and the population is a little over 3,000. The chief groups are Funafuti or Ellice, Nukulailai or Mitchell, Nurakita or Sophia, Nukufetau, Nui or Egg, Hudson and Niutao or Lynx. Nearly all the natives are Christians, Protestant missions having been long established in several of the islands. Those of Nui speak the language of the Gilbert islanders, and have a tradition that they came some generations ago from that group. All the others are of Samoan speech, and their tradition that they came 30 generations back from Samoa is supported by recent research. The islands have a plentiful rainfall and uniformly high temperatures. The coconut and pandanus are staple foods, and much copra is exported. "Babai" (a taro) is grown in increasing quantities and many fruits grow. Bêche-de-mer is plentiful in the

surrounding seas. Borings and soundings taken at Funafuti in 1897 indicate almost beyond doubt that the whole of this Polynesian region is an area of comparatively recent subsidence.

See *Geographical Journal*, passim; *Atoll of Funafuti: Borings into a Coral Reef* (Report of Coral Reef committee of Royal Society, London, 1904); and Stewart's *Handbook of the Pacific Isles.*

ELLICHPUR, an old Mohammedan capital in Berar, India, which was the headquarters of a British district now merged with the district of Amraoti. The abolition of the district has reduced the importance of the town, but a narrow gauge railway connects it with Martizapur on the main line to Bombay. It carries on a timber trade with Melghat and the Betul district. Pop. 23,899 (over 7,000 Mohammedans). There are many old Muslim families in reduced circumstances, but some revival of trade has followed the construction of the railway. It has several ginning factories and is connected by good roads with Amraoti and Chikalda. The adjacent civil station of Ellichpur (Paratwara), which includes the abandoned cantonment, has a population of 7,743 compared with 11,000 in 1872.

ELLICOTT, CHARLES JOHN (1819–1905), bishop of Gloucester, was born on April 25, 1819, at Whitwell, near Stamford, and educated at Oakham, Stamford, and St. John's college, Cambridge. He was elected a fellow of St. John's in 1845, but his fellowship lapsed on his marriage in 1848. After ten years in the living of Pilton, Rutlandshire, he became professor of New Testament exegesis at King's college, London. In 1859 he was Hulsean lecturer, and in 1860 professor, at Cambridge. In 1861 he was made dean of Exeter, and organized a diocesan training college there, and in 1863 was made bishop of Gloucester and Bristol. During the 42 years of his episcopate he helped to establish the Gloucester Theological college, and the Church Aid Society in Bristol (1867). He was secretary to the Lambeth conferences of 1867, 1878 and 1888, and registrar in 1898. He took an important part in the work of the royal commission on ritual and the rubrics (1867). In 1897, when the sees of Gloucester and Bristol were divided, Ellicott remained bishop of Gloucester, resigning on March 25, 1905. He died on Oct. 15, 1905.

His publications include: *Historical Lectures on the Life of Our Lord Jesus Christ* (1860, 6th ed. 1876); *Addresses on the Revised Version* (1901); *Christus Comprobatur* (1891); he also edited, with the collaboration of Plumptre, Sanday and others, *A New Testament Commentary for English Readers* (3 vols. 1878–79, 2nd ed. 2 vols. 1892–96), *An Old Testament Commentary* (5 vols., 1882–84 and 1884–92), and *The Complete Bible Commentary for English Readers* (7 vols. 1897, new ed. 1905).

ELLIOT, JANE (or JEAN) (1727–1805), poet, daughter of Sir G. Elliot, 2nd baronet of Miabo, was born at Minto House, Teviotdale, in 1727. By her courage and wit she saved her father from the Jacobites in 1745; but she is best known for her beautiful ballad "The Flowers of the Forest," which is said to have been written as the result of a wager with her brother, Gilbert Elliot, also an author. No other poems by Jane Elliot are known. She died on March 29, 1805.

ELLIOTSON, JOHN (1791–1868), English physician, was born at Southwark, London, on Oct. 29, 1791. He studied medicine at Edinburgh, Cambridge, and subsequently in London at St. Thomas's and Guy's hospitals. In 1831 he was elected professor of the principles and practice of physic in London university, and in 1834 he became physician to University college hospital. His interest in mesmerism eventually brought him into collision with the medical committee of the hospital, and he resigned his offices in 1838. In 1849 he founded a mesmeric hospital. He died in London on July 29, 1868. Elliotson was one of the first teachers in London to appreciate the value of clinical lecturing, and one of the earliest among British physicians to advocate the employment of the stethoscope. He contributed numerous papers to the *Transactions* of the Medico-Chirurgical Society, of which he was at one time president; he was founder and president of the Phrenological Society. W. M. Thackeray's *Pendennis* was dedicated to him.

ELLIOTT, EBENEZER (1781–1849), English poet, was born at Masborough in Yorkshire, the son of an ironmaster. At the age of 16 he entered his father's foundry, where he worked for seven years. In an autobiographical sketch printed in *The Athenaeum* (Jan. 12, 1850), he says he was entirely self-taught, and owed his poetical development to long country walks and a collection of books left to his father. His early poetry is of a romantic nature, and begins with *The Vernal Walk,* in imitation of Thomson, which was not successful. He and his father later lost all their money when the iron foundry failed, and he attributed this to the effect of the Corn Laws. He became an active Chartist, and his political interests produced a complete change in the character of his verse. The *Corn Law Rhymes* (1831) are notable for a vigorous denunciation of injustice and for vivid description. In 1833–35 he published *The Splendid Village; Corn Law Rhymes and Other Poems* (3 vols.). He retired from business in 1841 and died at Great Haughton on Dec. 1, 1849. In 1850 appeared *More Prose and Verse by the Corn Law Writer* (2 vols.). The sincerity of Elliott's poetry has saved it from the usual fate of political verse.

See an article by Carlyle in the *Edinburgh Review* (July, 1832); obituary notice in *Gentleman's Magazine* (Feb. 1850); "January Searle" (G. S. Phillips), *Life, Character and Genius of Ebenezer Elliott* (1850); J. Watkins, *Life, Poetry and Letters of Ebenezer Elliott* (1850); J. W. King, *Ebenezer Elliott* (Sheffield, 1854).

ELLIOTT, HOWARD (1860–1928), American railway manager, was born in New York city, Dec. 6, 1860. After graduating from the Lawrence scientific school, Harvard, in 1881, he was for several years a clerk in various offices of the Chicago, Burlington and Quincy Railroad. Later he was appointed general freight agent and then general manager of several lines belonging to the Burlington system. In 1902 he became second vice president of the company and the following year president of the Northern Pacific Railway. In 1913 he was made president of the New York, New Haven and Hartford Railroad and at the same time chairman of its board of directors. In 1917 he resigned and was made chairman of the committee on inter-corporate relations of the New Haven system, a position he retained until 1922. In 1917 he was nominated by the American Railway Association one of the six members of the railroads war board. In the same year he also became chairman of the executive committee of the Northern Pacific Railway Company, was president 1919–20 and then chairman of the board of directors. He took an active part in obtaining legislation from Congress for the protection of the railroads, urged higher freight rates and suggested the creation of a department of transportation, with a secretary in the cabinet. He was three times elected an overseer of Harvard college, and in 1927 served his fourth year as president of the board of overseers of Harvard. He died at Dennis, Mass., on July 8, 1928.

ELLIPSE, in geometry, a closed plane curve of second degree (order and class), or a conic section (*q.v.*) made by a plane cutting all elements of a circular cone, considered either as solid or as surface. It may be regarded either as the plane area enclosed or preferably as its bounding curve. In fig. 1, OVE represents the trace of a cone cut through its axis by the plane of the paper; and OV, OM, OE, etc., represent the positions of a plane, at right-angles to the plane of the paper, rotating about O. In the position OV, the ellipse collapses into a double line OV; in the middle position OM it becomes a circle; in position OP, parallel to the opposite element VM, the section expands into a parabola; on further turning, in position OH, it becomes an hyperbola. This is the view taken by Apollonius (*c.* 220 B.C.). Menaechmus (*c.* 350 B.C.) probably conceived the ellipse as made by a plane perpendicular to OV, the cone-angle V being acute. On V's retiring to infinity (∞), the cone becomes a cylinder (*q.v.*), but the section remains an ellipse, the parabola becoming a pair of parallel lines.

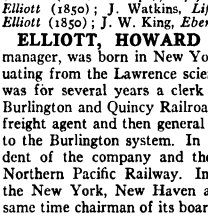

FIG. 1.—FORMS OF AN ELLIPSE

Viewed solely as a plane curve, the ellipse may be variously defined by some distinctive property. Most simply, it is the compression of a circle $x'^2+y'^2=a^2$ (called the *major* or *auxiliary*

circle) by the affine transformation $x=x'$, $y=\frac{b}{a}y'$. Suppose the whole plane to settle toward the horizontal x-axis (fig. 2) every vertical line shrinking uniformly in the ratio $b:a$; then the circle $x^2+y^2=a^2$ shrinks into the ellipse $x^2/a^2+y^2/b^2=1$.

Imagine the shadow cast by a circular disc, in sunlight perpendicular to a vertical wall, as the disc rotates round a horizontal

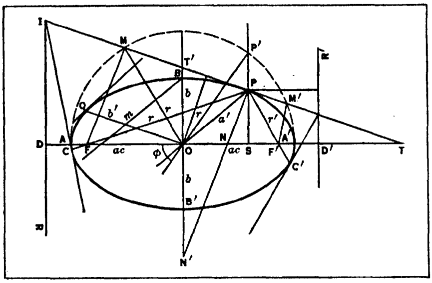

FIG. 2.—SHOWING HOW THE COMPRESSED CIRCLE, $x^2+y^2=a^2$ SHRINKS INTO THE ELLIPSE $x^2/a^2+y^2/b^2=1$

diameter parallel to the wall. In the shadow the vertical chords are all shortened, being multiplied by $\sin\theta$ (the slope of the disc to the light-rays). It is seen instantly that the circle-area πa^2 is reduced in the same ratio b/a and becomes πab for the ellipse, and that any tangent to the circle becomes a tangent to the ellipse, merely rotating about its intersection T with the axis.

The central vertical BB' is called the *minor axis*, and the circle about it as diameter is called the *minor circle*. The circle of radius a about B as centre cuts the major axis AA' at F and F', points of special importance (called foci); $OF=OF'=\sqrt{(a^2-b^2)}$. If we call this ae, we have

$$e=\sqrt{(1-b^2/a^2)},\ 1-e^2=b^2/a^2;$$

e is the *eccentricity*, and ae the *linear eccentricity*. If P' and P be any two corresponding points on the major circle and the ellipse, and S the common foot of the ordinates $P'S$, PS, then the angle SOP' is termed the *eccentric angle* ϵ of P. Then

$$F'P^2=r'^2=(ae-x)^2+y^2=(ae-x)^2+(1-e^2)(a^2-x^2)=(a-ex)^2,$$
$$\text{and } r'=a-ex.$$

Similarly, $FP=r=a+ex$; hence $r+r'=2a$; *i.e., the sum of the distances of any point* (P) *of an ellipse from two fixed points* (F, F′) *is a constant* (the major axis, $2a$). This is the ordinary definition of an ellipse. If we think of F' as a *pole*; then its *polar* (the locus of the intersection I of tangents at the ends of a chord $C'F'C$) will be

$$aex/a^2+0\cdot y/b^2=1,$$

or $x=a/e$, the vertical $D'R'$ (*directrix*); with the points F' and D' in involution, OF'. $OD'=OA^2=a^2$. Hence the distance d, of any point P of the ellipse from $D'R'$, is $a/e-x$, which is equal to r/e; or $e=r/d$; *i.e., the ratio of the distances of any point of the ellipse from a focus* (F') *and the directrix is a constant, the eccentricity* (<1), which gives the preferred definition of an ellipse.

Conjugate diameters in the circle $x^2+y^2=a^2$, each bisecting all chords parallel to the other, do not remain mutually perpendicular in an ellipse, being pressed down towards the axis AA'; but they still bisect as in the circle, since all parallel lengths are shortened throughout in the same ratio, varying with the direction of the chord. Hence the equation of the ellipse referred to conjugate diameters $2a'$, $2b'$ as co-ordinate axes is $x^2/a'^2+y^2/b'^2=1$. It is easily shown that $a'^2+b'^2=a^2+b^2$, a constant. Again, if ϕ be the angle between two conjugates, then $\sin\phi=ab/a'b'$, or $4a'b'\sin\phi=4ab$; *i.e., the parallelogram of tangents at the ends of conjugate diameters is constant in area.*

The *tangent* and *normal* at any point P bisect the angles between the focal radii FP, $F'P$; hence any ray from F is reflected at P through F' and then back to F, and all rays from either focus converge in reflection, on the other; a fact of significance in the study of light, sound, etc. Any perpendicular from a focus on a tangent meets it on the major circle; the product of two such perpendiculars (from F, F') is b^2, a constant. From any outside point Q two tangents QT, QT' may be drawn to E; then the angles of these tangents with focal radii to Q will be equal; *i.e.*, $\angle TQF=\angle T'QF'$. If $\angle\ TQT'$ be a right angle, then Q is on the *director circle* $x^2+y^2=a^2+b^2$. This follows at once from the equation of the tangent, $y=mx+\sqrt{(m^2a^2+b^2)}$. To obtain the equation of the perpendicular tangent, change m into $-1/m$, then eliminate m. Various simple relations connect the subtangents and subnormals.

The *area* of *an ellipse* is πab. To find the *arc-length* involves the use of elliptic integrals and their Abelian inverses, elliptic functions, and doubly periodic functions in general (*see* ELLIPTIC FUNCTIONS.) Kepler's approximation $\pi(a+b)$ is about $\frac{1}{300}$ too large, and $\pi\sqrt{a^2+b^2}$ is about as much too small; their mean errs by about $\frac{1}{3000}$.

Construction and Analysis.—An ellipse may be drawn by fastening the ends of a cord $2a$ units in length at F and F', and then passing a pencil point along the cord held taut by the point (all in the same plane). Alternatively any number of points may be found as follows: Draw concentric major and minor circles (radii a and b) about O; and any radius cutting them at P and Q. Through P draw the vertical chord VV', and through Q the horizontal chord HH'; these meet in a point M on the ellipse, for the x of V on the circle is unchanged, and y is shortened in ratio b/a.

To find the axes of an ellipse, bisect two pairs of parallel chords; the bisectors will be diameters meeting in the centre O. About O draw any circle cutting the ellipse in four points; these are obviously symmetrical with respect to the axes, which are the mid-parallels to the sides of their rectangle. The foci are F and F' on the major axis AA' ($2a$), each at a distance of a from the ends B, B' of the minor axis. The directrices are parallel to BB', and each is distant $d=a/e=a^2/\sqrt{(a^2-b^2)}$ = the intercept between the axes on a parallel to BF, through A. The ellipse is conspicuous in astronomy as the path of a single mass-centre about another obeying the Newtonian *law of inverse squares*. The attraction of other planets perturbs this path of any one planet round the central sun. (*See* also PROJECTIVE GEOMETRY.)

(W. B. SM.)

ELLIPSOGRAPHS. The earliest method of drawing ellipses is by means of a stretched string, a device still adopted by gardeners and others in setting out large ellipses. It is based on the property of the ellipse that if P is any point on the curve and F,F′ are the two foci, then PF+PF′ is of constant value, equal to the length AA′ of the ellipse. The positions of F and F′ on the major axis AA′ of the ellipse are found by setting off BF and BF′ each equal to half the length of the ellipse. The ends of a piece of string are secured at F and F′ in such a way that the length of the free portion FPF′ is equal to that of the ellipse. A pencil or other marking point P pressed outwards against the string, if moved so as to keep the string always taut, will draw the required ellipse. Though quite satisfactory for such work as setting out the shape of an elliptical flower-bed, the difficulty due to variable stretching of the string renders it unsuitable for accurate work. Various simple arrangements for facilitating the application of this method to the drawing of small ellipses have, however, been devised by W. F. Stanley, H. V. Hazard (1884), V. E. Contonze (1895), Professor Honey, R. Ramm and others.

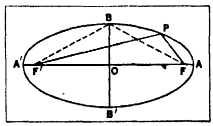

FIG. 1

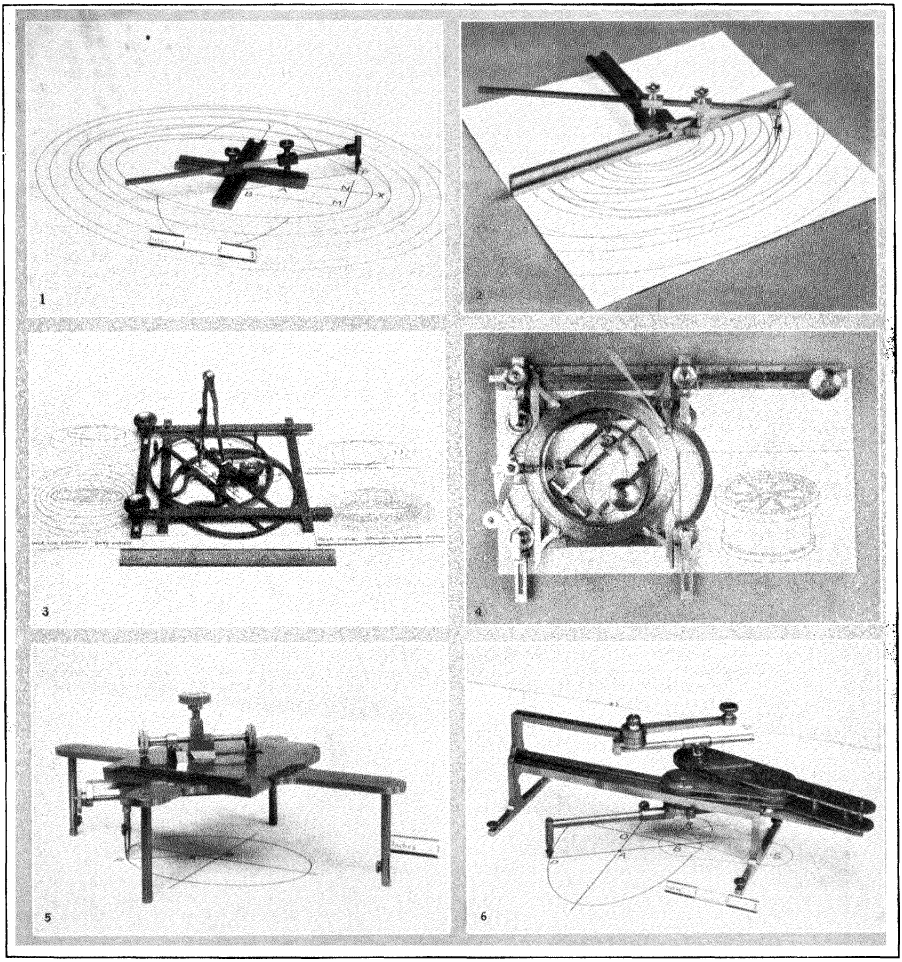
The most simple and most widely used instruments for drawing ellipses such as are required in ordinary drawing office practice is the *elliptic trammel*. When two points A, B, a fixed distance apart, are constrained to move along two mutually perpendicular straight lines XX,YY, any point P in the line AB, or in that line produced, describes an ellipse. On this principle the elliptic



BY COURTESY OF THE DIRECTOR OF THE SCIENCE MUSEUM, SOUTH KENSINGTON

DEVELOPMENT AND FORMS OF THE ELLIPSOGRAPH

1. Elliptic trammel. The cross-shaped, grooved base is held firmly by needle points upon the paper. The arm is adjusted by knurled screws above sliders, which move in the grooves of base. The inked pen is moved in an elliptical curve by the knob at right end of arm
2. Semi-elliptic trammel, a modification of the instrument shown in fig. 1. By adjusting the rocker arm, which moves in the two grooves of the base, one half of an elliptical curve is drawn. Reversing the instrument upon the paper, with the same adjustment, the other half of curve is made
3. Farey's ellipsograph, 1810. Two circular slides, moving as one piece, guide the compass point in tracing the ellipse. Knurled thumb screw at right of compass regulates the figure drawn. Figures traced at right and left show range of the instrument as compared with elliptic trammels
4. Improved Farey instrument, 1817. White knob at lower left moves the handle, geared to upper slider, which permits steadier rotation between the two friction wheels. Adjustment is made along the boxwood rule at top, fastened to the paper upon which the figure is to be drawn
5. James Finney's ellipsograph, 1855, with Stanley's improvements. Combination of circular and rectilinear motion occurs in this instrument. The milled head screws (above) are used for determining the radius; same at lower left for setting the pen
6. Edward Burstow's ellipsograph, 1871. By turning the handle at top, motion is transmitted through rocker arm to chain or wheel gearing in the moving arm at right, which slides in slotted frame of the instrument. Correct curve is transmitted through drawing arm to pen and paper below

trammel provides a convenient means of describing ellipses of various sizes and proportions. In the example shown in Plate I., fig. 1, a cross-shaped piece of metal has two undercut grooves at right angles to each other, and is fixed to the paper by needle-points underneath. Two sliders fitting in the grooves carry heads, through which passes a bar to which each head can be clamped. The describing pen or pencil is attached to the end of the bar.

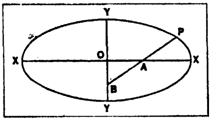


FIG. 2

Ellipses of a width less than the length of each groove cannot be drawn.

In the *semi-elliptic trammel* this difficulty is overcome to a certain extent by cutting away one arm of the cross. If a complete ellipse is required, the two halves of the curve must be drawn separately. An example is shown in Plate I., fig. 2. The long groove is in a plane below the short groove, and along the front of the instrument; the slides can therefore be made long so as to ensure steady working.

For drawing ellipses of small size, John Farey in 1810 devised his modification of the ordinary trammel, since known as *Farey's ellipsograph.* Plate I., fig. 3 shows the original instrument made by him and given in 1812 to the Society of Arts, who awarded him a gold medal for the invention. The grooves of the ordinary trammel are replaced by two pairs of parallel bars fixed at right angles to each other. Each of the two slides takes the form of a circular ring about 4 inches in diameter, and the distance between the centres of the rings can be varied from zero to about 1·2 inches by means of a small rack and pinion with milled head. This is the only relative motion possible between the two circles, which move as one rigid piece when an ellipse is being drawn. Attached to the upper circle is a swivel socket, in which the end of one arm of an ordinary pair of bow compasses may be fixed; this affords an easy and quick means of adjusting the position of the drawing point. Clamped to the frame by two milled-headed screws is a ruler having two needle points projecting from its under surface; this ruler being placed approximately in position, the frame can be adjusted exactly to the right position for drawing the required ellipse. The action of the instrument may be understood by consideration of the equivalent trammel shown drawn underneath the instrument in the illustration.

Farey improved the original form of the instrument by the addition of various adjustments. The example shown in Plate I., fig. 4, which was made in 1817, contains the following improvements. Steadier rotation of the instrument is secured by means of a handle and small pinion gearing with a toothed wheel attached to the upper slider, which slides between two pairs of friction wheels. For drawing ellipses whose major axes are parallel, the instrument is attached to a brass plate which, by means of rack and pinion, can slide along a groove in a boxwood rule 14in. long. This rule is divided into inches and twentieths, and is kept fixed to the paper by three projecting needle-points underneath. Instead of the ordinary pair of compasses for varying the radius, an arm is provided carrying a rack-and-pinion adjustment for the pen.

Another important addition, first introduced by Farey in 1813, is a dividing plate for facilitating such work as the drawing of orthogonal projections of the divisions on divided circles, in drawings such as that shown with the instrument. The dividing plate on this instrument is provided with five sets of holes, giving 360, 96, 90, 72 and 60 divisions to the complete circle.

With such instruments ellipses were often drawn by a diamond point direct on copper plates, and the high standard of performances of the instrument is indicated by the excellence of the engravings of mathematical instruments, etc., made by Farey and others, which form illustrations to scientific papers of that period. Other designers of efficient ellipsographs about this time were W. Cubitt (1817) and Joseph Clement (1818).

In another type of ellipsograph, the combination of a circular with a rectilinear motion forms the basis of the design. In the ordinary trammel, during the operation of drawing an ellipse, the point C, midway between A and B, describes a circle round O as centre, and the angle COA is always equal to the angle CAO. If an arm OC, attached to AB and capable of rotation about O, be provided, one rectilinear guide may be dispensed with.

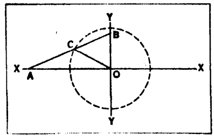

FIG. 3

James Finney's ellipsograph (1855), shown in Plate I., fig. 5 with Stanley's improvements, is of the overhead type on this principle. It is provided with milled-headed screw adjustments for varying the radius and setting the pen. Edward Burstow in his ellipsograph of 1871 used a chain or wheel gearing to effect the combination of motions, only one rectilinear slide being employed.

If in addition to providing for the circular motion of C about O as centre, other gearing carried on OC and CA ensures that CA moves so that the angles CAO and COA are always equal, the single rectilinear slide becomes unnecessary. A few instruments of this type have been constructed, since about 1860; one designed by Frank J. Gray in 1901 is described in detail in the Journal of the Society of Arts, 1902.

When an ordinary drawing pen is used as the describing point in the instruments previously mentioned, the lines drawn are not of uniform thickness unless the pen is guided so that its nibs are kept tangential to the curve. It will be seen from the adjacent diagram that if AD and BD be drawn parallel to the arms of the trammel or equivalent trammel in any ellipsograph, D is the instantaneous centre of motion of AB and of any point P in AB produced. As OD is of constant length, D describes a circle about O as centre, and it is possible to arrange for a rod PD, passing through a sleeve fixed to the arm OD at D, and attached to the pen at P, to keep the pen always tangential to the curve. On this principle a steering device was applied to the ellipsograph by Prof. Alexander, and by F. J. Gray in his instrument of 1901.

ELLIPSOID, a closed surface of the second degree. Its plane sections are ellipses, its central (rectangular) equation being $x^2/a^2+y^2/b^2+z^2/c^2=1$. Obviously it may be formed after the analogy of the ellipse (*q.v.*) by *affine transformation* (*see* AFFINE GEOMETRY) of the sphere $x^2+y^2+z^2=a^2$, by compressing uniformly, in the ratios b/a and c/a, all y and z coordinates, two sets of mutually perpendicular chords, also perpendicular to OX.

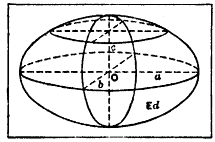

FIG. 1

Less vividly it may be imagined as the path of a varying ellipse always parallel to a fixed plane (XY), its vertices moving on two ellipses in two perpendicular planes, YZ and ZX (fig. 1). For any equality among a, b, c, the surface becomes a *spheroid.* (*See* CONOID.) The elliptic plane sections become circular for two directions. For suppose $a>b>c$, then the plane XY cuts out the ellipse $x^2/a^2+y^2/b^2=1$, having the major and minor axes $2a$, $2b$. Turn the plane about Y or $2b$, the minor axis $2b$ of the ellipse remains unchanged while the major axis decreases from $2a$ to $2c$, for on turning through 90° the ellipse becomes

$y^2/b^2+z^2/c^2=1$. At some stage $2b$ must have ceased to be *minor* and become *major;* at that stage the axes of the ellipse were equal, both being $2b$, and the ellipse was a circle, and so were all parallel sections. The sections shrink into *cyclic points* as the planes become tangent. If θ be the slope of the plane to the greatest axis $2a$ the opposite slope $-\theta$ would yield a like result; hence there two sets of cyclic sections and four cyclic points. (*See* fig. 2.)

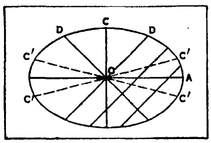

FIG. 2

The volume of the ellipsoid is that of the major sphere reduced in the ratio bc/a^2. In MECHANICS (*q.v.*), the ellipsoid plays an important rôle in the study of moments and inertia. (*See* SURFACE and MATHEMATICAL MODELS.)

ELLIPTIC FUNCTIONS. It is a familiar result of elementary integral calculus that, if R is a linear or quadratic function of a variable x, $\sqrt{R}$, $1/\sqrt{R}$ and, more generally, $f(x,\sqrt{R})$, where f is any rational function, can be integrated by means of elementary functions. In the next higher case, when R is a cubic or quartic with no repeated factor, no such integration is possible. It was gradually recognized by mathematicians of the 18th century that such integrals were essentially new functions requiring special investigation. Particular cases of $\int\sqrt{R}dx$ and of $\int(1/\sqrt{R})dx$ occurred respectively in the problem of finding the length of an arc of an ellipse, and in that of the motion of a pendulum, and on account of the former problem the name *elliptic* was given to the new functions. Some isolated results connecting two or more arcs of ellipses or of other curves were obtained in the first half of the 18th century, and an important formula connecting two integrals was discovered in 1761 by Leonhard Euler (1707–83), a formula equivalent to one of what we now call addition theorems (sec. 3). An algebraic transformation of one elliptic integral into another, which was afterwards found to be of great importance for numerical calculation, was given in 1775 by John Landen (1719–90), in a geometrical form.

1. Elliptic Integrals.—The first systematic treatment of the new functions is due to Adrien Marie Legendre (1752–1833), whose main results were embodied in the great *Traité des fonctions elliptiques et des intégrales Eulériennes* (1825–28). In particular Legendre showed that any integral of the form $\int f(x\sqrt{R})dx$, where, as before, R is a cubic or quartic and f is a rational function, can be reduced to the sum of an elementary function and of constant multiples of integrals of the three standard forms

$$\int\frac{d\phi}{\Delta(\phi)},\qquad\int\Delta(\phi)d\phi,\qquad\int\frac{d\phi}{(1+n\sin^2\phi)\Delta(\phi)},$$

where $\Delta(\phi)=\sqrt{(1-k^2\sin^2\phi)}$, and k, n are constants. These integrals are called Legendre's standard (or normal) elliptic integrals of the first, second and third kinds, respectively; and, if the integration is from 0 to ϕ, are denoted by $F(k,\phi)$, $E(k,\phi)$, $\Pi(n,k,\phi)$; ϕ is called the *amplitude*, k the *modulus*, and n the *parameter*. If the original integral is *real*, k can be taken to be a positive number less than 1, and n to be real; if the restriction to reality is removed, k, n may be any real or complex numbers, subject to the exceptions that if k^2 is 0 or 1 the integrals are elementary functions, and that if n is 0 the third integral reduces to the first. The integrals may be expressed in the equivalent algebraic forms

$$\int\frac{dx}{\sqrt{R_1}},\qquad\int\frac{\sqrt{(1-k^2x^2)}}{\sqrt{(1-x^2)}}dx,\qquad\int\frac{dx}{(1+nx^2)\sqrt{R_1}},$$

where $x=\sin\phi$ and $R_1=(1-x^2)(1-k^2x^2)$; R_1 may be called Legendre's *normal form* of the fundamental quartic.

The integrals in their algebraic forms have the functionally important properties that the first is finite for all real or complex values of x (including infinity), the second is simply-infinite (*i.e.* has a *pole* of order 1) for $x=\infty$, and the third is logarithmically-infinite for $x^2=-1/n$. If $\phi=\pi/2$, we have the corresponding *complete integrals*, sometimes denoted by F_1, E_1, Π_1; but the two former are more commonly called K and E respectively. If k is replaced by $k'=\sqrt{(1-k^2)}$, the corresponding complete integrals are denoted by K' and E'. It should be noticed that $F(k,\phi)$ and $E(k,\phi)$ are functions of two independent arguments k and ϕ, $\Pi(n,k,\phi)$ of three arguments; but k, n usually (though not invariably) remain constants throughout any particular investigation. Legendre gave extensive numerical tables of the integrals of the first and second kinds, which are the basis of nearly all modern tables (*see* bibliography).

Other standard forms of the integrals have been used by other writers; it is enough to give the important form of the integral of the first kind

$$\int_z^\infty\frac{dz}{\sqrt{(4z^3-g_2z-g_3)}}$$

(where g_2 and g_3 are constants), first systematically used at a much later date by Karl Theodor Wilhelm Weierstrass (1815–97). *See* sec. 6.

2. Inversion: Elliptic Functions.—Before Legendre's *Traité* was finished, the subject was revolutionized by Niels Henrik Abel (1802–29), working in close connection with Carl Gustav Jacob Jacobi (1804–51). In 1825 Abel *inverted* the relation between the integral of the first kind $F(k,\phi)$ and its amplitude ϕ, by treating ϕ as a function of the integral, instead of following Legendre in treating the integral as a function of ϕ. In Jacobi's notation, if $u=F(k,\phi)$ then

$$\phi=\mathrm{am}\,u,\quad\sin\phi=\sin\mathrm{am}\,u,\quad\cos\phi=\cos\mathrm{am}\,u,\quad\sqrt{(1-k^2\sin^2\phi)}=\Delta\mathrm{am}\,u.$$

The three latter functions so obtained, now more commonly written in the abbreviated forms sn u, cn u, dn u, or, if it is desirable to express the modulus k explicitly, sn(u,k) cn(u,k), dn(u,k), are called Jacobi's *elliptic functions*, as distinguished from Legendre's *elliptic integrals*, which, however, Legendre himself called *fonctions elliptiques*. Abel immediately recognized as a fundamental property the existence, in the case of each function, of two independent periods, which are respectively real and pure-imaginary in the standard case when $0<k^2<1$. In the particular degenerate case $k^2=0$, sn u, cn u become the trigonometrical functions sin u, cos u, with the real period 2π and dn u becomes 1; when $k^2=1$, sn u becomes the hyperbolic function tanh u, with the imaginary period $i\pi$, and each of cn u, dn u becomes sec u, with the period $2i\pi$. It is now known that many of the fundamental results of Abel and Jacobi had been anticipated, but not published, by Carl Friedrich Gauss (1777–1855).

It is by no means evident that the elliptic functions thus provisionally defined are definite functions of the argument u, still less that they are one-valued functions for complex as well as real values of u, as may be illustrated by the fact that in the next higher case, when the quartic is replaced by a quintic, the process of inversion breaks down completely. A satisfactory proof that the elliptic functions, as defined by inversion of an integral, are one-valued analytic functions only became possible after further development of the theory of functions of a complex variable. From one point of view the essential simplification due to inversion is that elliptic integrals, which are infinitely-many-valued functions, are replaced by one-valued functions; as in trigonometry it is obviously much simpler to work with the one-valued function $x=\sin\theta$ rather than with the many-valued inverse function $\theta=\arcsin x$.

3. Elementary Properties of Jacobi's Elliptic Functions.—Jacobi's book *Fundamenta nova theoriae functionum ellipticarum* (1829) contains, among other results, the main properties of the new functions and of some allied functions. The derivatives of sn u, cn u, dn u follow at once from the definitions. The very important formulae called *addition-theorems* express sn $(u+v)$, etc. as rational functions of sn u, cn u, dn u and sn v, cn v, dn v, and are analogous to the familiar trigonometrical formulae for sin $(A+B)$, etc. If u is increased by the complete integral K, it follows from the addition theorem that sn u is converted into a simple function of cn u, dn u, and if u is increased by $2K$, sn u merely changes sign, so that sn u is periodic in $4K$; if K' is the

complete integral corresponding to the complementary modulus k', iK' has similar properties and in particular sn u is periodic in $2iK'$; similarly for cn u, dn u. The transformations employed show that the three functions are infinite of order 1 (*i.e.*, have simple poles) when $u=iK'$, and, more generally, if u differs from iK' by any integral combination of $2K$, $2iK'$ of the form $2mK+2niK'$ where m and n are integers. A very large number of formulae of interest follow immediately from the addition theorems and the periodicity.

The integrals of the second and third kinds are now expressed in terms of the new variable u, the integral of the first kind. Modifying Legendre's choice of functions, Jacobi replaced $E(k, \phi)$ by $E(u, k)=\int_0^u dn^2u\,du$, and introduced an allied function $z(u)=E(u)-(E/K)u$, where E is Legendre's complete integral of the second kind; Legendre's $\Pi(n, k, \phi)$ is replaced by

$$\Pi(u, a, k) = \int_0^u \frac{k^2\text{sn}a \text{ cn}a \text{ dn}a \text{ sn}^2u\,du}{1-k^2\text{sn}^2 a \text{ sn}^2 u}.$$

4. Doubly-periodic Functions.—Jacobi's sn u, cn u, dn u are simple cases of a more general class of functions having the same or similar fundamental properties. We can take any two numbers 2ω, $2\omega'$ as periods, subject to the one restriction that $\tau\equiv\omega'/\omega$ is not real; then any one-valued analytical function $f(u)$, which is doubly periodic in 2ω, $2\omega'$, so that

$$f(u+2\omega)=f(u+2\omega')=f(u),$$

and has no singularities other than poles for any finite value of u, may be called an *elliptic function*. It is convenient to use the geometrical representation of complex numbers (*q.v.*) by points in a plane (the Argand diagram); any parallelogram with vertices at α, $\alpha+2\omega$, $\alpha+2\omega+2\omega'$, $\alpha+2\omega'$ (α arbitrary), is called a *parallelogram of the periods*; if we know the properties of $f(u)$ throughout any one parallelogram, then from the periodicity we know its properties everywhere, so that it is enough to study one parallelogram.

A number of important general properties of elliptic functions were established by Joseph Liouville (1809–82), mainly by the method of contour-integration; in particular

(i.) an elliptic function $f(u)$ which has no pole in a parallelogram of the periods is a constant;

(ii.) the sum of the *residues* of $f(u)$ at the poles in a parallelogram is zero;

(iii.) $f(u)$ has at least two poles, or a multiple pole, in a parallelogram;

(iv.) the number of poles in a parallelogram is equal to the number of zeros and is also equal to the number of points at which the function has any assigned value;

(v.) the sum of the values of u at the poles in a parallelogram is equal to the sum of the values of u at the zeros or differs from it by some period.

(These theorems require obvious modifications, if the poles, etc., are multiple, or if any of them lie on the boundary of the parallelogram, and in the trivial case when $f(u)$ is merely a constant). Liouville's theory gives simple proofs of important properties of the elliptic functions as well as of many elementary identities; *e.g.*, to prove the identity of two functions $f(u)$, $\phi(u)$, it is enough to prove (1) that the periods are the same, (2) that in any parallelogram they have the same poles and zeros (of the same order), so that by (i.) their quotient is a constant and (3) that the quotient is 1 for some particular value of u.

5. The Theta-Functions.—In the *Fundamenta Nova* Jacobi introduced four allied functions $\theta(u)$, $\theta(u+K)$, $H(u)$, $H(u+K)$, each of which is *holomorphic*, *i.e.*, is a one-valued analytic function with no singularity except at infinity; and showed that the quotients of $H(u)$, $H(u+K)$, $\theta(u+K)$ by $\theta(u)$ are constant multiples of sn u, cn u, dn u. He also showed that the integral of the third kind can be expressed in terms of these new functions.

In lectures (published posthumously) he used modifications of these functions as a basis for the whole theory. Taking one period arbitrarily to be π and the other to be $\pi\tau$ where τ is an arbitrary complex number $\alpha+i\beta$, subject only to the condition that β is positive, we define four functions $\theta_r(x)$, $(r=0, 1, 2, 3)$ as series of sines or cosines of multiples of a variable x, the coefficients being of the form $\pm 2\rho^{n^2}$, where $\rho=e^{\pi i\tau}$ and n is an integer or half an odd integer. From the condition imposed on $\tau_1|\rho|<1$ the series converge for all values of x, and, except when $|\rho|$ is near 1, with great rapidity. The addition of a half-period to x converts any θ into another θ multiplied by a simple factor, and the addition of a period merely multiplies any θ by a simple factor, in such a way that the quotient of any two θ's is doubly-periodic.

By multiplying four of the series together and rearranging, Jacobi obtains a remarkable system of *theta-product formulae*, which are, in the first instance, linear relations between products of four θ's of eight variables, four of which are independent. By specializing the variables, a great number of interesting and important relations between θ's of 4, 3, 2, 1 or 0 independent variables are obtained. Certain of these formulae yield algebraical addition theorems for quotients of two θ's, and differentiation follows by a simple limiting process; and finally there is constructed, in the form of a quotient of θ's, a function which satisfies the condition which defines sn u regarded as the inverse of the elliptic integral of the first kind. The process is entirely independent of any properties of the elliptic functions themselves, and is thus an independent method of solving the inversion problem (sec. 2), and incidentally gives most of the fundamental properties of Jacobi's elliptic functions.

The θ's are also expressible as singly-infinite products of trigonometrical factors, in forms from which the zeros are at once evident; sn u, cn u, dn u and various simple combinations of them, as well as $Z(u)$ are expressible as trigonometrical series, which unlike the θ's have only a limited range of convergence; and the constants k, k', K, etc. are expressible in a variety of forms as infinite products involving ρ, as ratios of series in ρ, or as series in ρ.

6. The Weierstrassian Theory.—By inverting the integral of the first kind in the Weierstrassian form (sec. 1), we obtain an elliptic function $\wp(u)$ which, unlike the Jacobian functions, has a single pole of order 2 in any parallelogram. The theory is however more simply developed if we define $\wp(u)$ not by inversion, but as a double-series, which converges everywhere except at the poles, has two periods chosen arbitrarily subject to the condition that their ratio is not real, and has a double pole in each parallelogram. An easy application of Liouville's method gives the formula

$$\wp'(u) = \sqrt{\{4\wp^3(u)-g_2\wp(u)-g_3\}},$$

where g_2, g_3 are defined as series involving only the periods, and a solution of the inversion problem follows. Closely connected with $\wp(u)$ are the functions $\zeta(u)$, defined as a doubly-infinite series with simple poles, and $\sigma(u)$ defined as a doubly-infinite product with no singularities. The three functions are connected by the equations

$$\zeta'(u)=-\wp(u), \quad \sigma'(u)/\sigma(u)=\zeta(u).$$

Neither ζ nor σ is periodic, but they undergo simple changes when u is increased by a period; ζ, which is closely allied to Jacobi's z, can be taken as the integral of the second kind, and the integral of the third kind is simply expressible in terms of $\sigma(u)$.

The Liouville theory and simple algebra lead very easily to the addition-theorem for $\wp(u)$, formulae for the addition of half-periods, and to many other results, the development being in general much more symmetrical and elegant than for the Jacobian functions. With $\sigma(u)$ are associated three other functions $\sigma_r(u)$, $(r=1, 2, 3)$, these four functions being closely related to the four θ's. The Weierstrassian and Jacobian functions are connected by equations of the form

$$\wp(u)=A+B/\text{sn}^2(bu),$$
$$\sigma(u)=Ce^{au^2}\theta_1(cu),$$

(with similar formulae for the other σ's), A, B, C, a, b, c, being

constants; and the properties of either set of functions can be derived from the others.

Any elliptic function $f(u)$ can be expressed in any one of three standard forms:—

(i.) as a product of σ's, divided by another product of σ's,
(ii.) as a linear combination of ζ's and their derivatives,
(iii.) as a rational function of $\wp(u)$ and $\wp'(u)$.

From the second form the integral of $f(u)$ is at once expressible in terms of σ and ζ.

7. **The Theory of Transformation,** which originated with Abel and Jacobi as the problem of algebraic transformation of one elliptic integral into another, has developed into a very extensive subject, intimately connected on one side with algebraic equations and *groups* (*q.v.*), on another with the theory of numbers (*see* NUMBERS, THEORY OF). It lies outside our present scope in this article.

8. **Applications.**—As elliptic integrals or functions are required for the integration of the square root of a cubic or quartic they necessarily occur in many mathematical problems. Among these problems are:

In differential equations: the integration of Lamé's equation, and of Briot and Bouquet's equation $f(y, dy/dx)=0$;

In geometry: the arc of an ellipse, hyperbola, lemniscate; the parametric representation of the coordinates of a point on a non-singular, plane, cubic curve, or more generally on any curve of genus 1; Poncelet's polygons inscribed in one conic, circumscribed to another; the surface of an oblique cone and of an ellipsoid; geodesics on a quadric of revolution and umbilical geodesics on a general quadric;

In physics: the elastica, the motion of a projectile under a resistance varying as the cube of the velocity, the simple and spherical pendulums, the motion of a rigid body under no forces, the symmetrical top; the potential of an ellipsoid; various potential problems in which occurs a rectangular boundary, or various other rectilinear boundaries.

Svenska Ak.*, vol. 25 (1900); tables to 4 places in Jahnke and Emde, *Funktionentafeln,* and in Hoüel *Recueil de formules et de tables numériques.* Tables facilitating the calculation of K, E to 8 places are given by G. Witt in *Astronomische Nachrichten* (vol. 165).

Tables of log ρ to 5 places are given by Jacobi in *Crelle's Journal* vol. 26 (reprinted in *Opuscula Mathematica,* vol. i., and in *Gesammelte Werke* vol. i.), by Bertrand and by Lévy; to 4 places by Bohlin, Jahnke and Emde, and by Hoüel. Tables of the θ's as well as of $F(k,\phi)$, $E(k,\phi)$ to 10 places, are given by R. L. Hippisley, *Smithsonian Miscellaneous Collections* (vol. 74, no. 1, 1922), and of the θ's and their logarithmic derivatives to 4 places by Jahnke and Emde and by Hoüel. Tables, mostly to 5 places, of $\wp(u)\ \wp^1(u), \zeta(u)$, $\sigma(u)$ for the special case $g_2=0$, $g_3=1$, were calculated by A. G. Hadcock for a paper by Greenhill in *Proceedings of Royal Artillery Institution,* (1889) and reprinted to 4 places by Jahnke and Emde.

(A. BER.)

ELLIPTICITY, in astronomy, deviation from a circular or spherical form; applied to the elliptic orbits of heavenly bodies, or the spheroidal form of such bodies.

ELLIS (originally SHARPE), **ALEXANDER JOHN** (1814–1890), English philologist, mathematician, musician and writer on phonetics, was born at Hoxton, London, on June 14, 1814. He was educated at Shrewsbury, Eton and Trinity College, Cambridge, and took his degree in high mathematical honours. He was the first in England to reduce the study of phonetics to a science. His most important work, to which the greater part of his life was devoted, is *On Early English Pronunciation, with special reference to Shakespeare and Chaucer* (1869–89). He had long been associated with Isaac Pitman in his attempts to reform English spelling, and published *A Plea for Phonotypy and Phonography* (1845) and *A Plea for Phonetic Spelling* (1848); and contributed the articles on "Phonetics" and "Speech-sounds" to the 9th edition of the *Encyclopædia Britannica.* He died in London on Oct. 28, 1890.

ELLIS, GEORGE (1753–1815), English author, was educated at Westminster school and at Trinity college, Cambridge. He contributed to the *Rolliad* and the *Probationary Odes* satires against Pitt's administration. In 1797 he went to Lille as secretary to the embassy. He continued to write political satires in the *Anti-Jacobin,* which he founded with George Canning and William Gifford. For some years before the *Anti-Jacobin* was started Ellis had been studying Early English literature, in which he was one of the first to arouse interest. He rendered a very great service to English literature by his *Specimens of the Early English Poets* (1790) and his *Specimens of Early English Metrical Romances* (1805). He also edited G. L. Way's translation of select *Fabliaux* in 1796. Ellis was an intimate friend of Sir Walter Scott, who styled him "the first converser I ever saw." Some of the correspondence between them is to be found in Lockhart's *Life.*

ELLIS, SIR HENRY (1777–1869), English antiquary, was born in London on Nov. 29, 1777. Educated at Merchant Taylor's school, and at St. John's college, Oxford, he entered the British Museum in 1800. From 1827 to 1856 he was chief librarian. He died on Jan. 15, 1869. His principal works are: a new edition of Brand's *Popular Antiquities* (1813); *Introduction to Domesday Book* (1833); and *Original Letters Illustrative of English History* (first series, 1824; second series, 1827; third series, 1846) compiled chiefly from manuscripts in the British Museum and the State Paper office.

ELLIS, HENRY HAVELOCK (1859–), British psychologist, was born at Croydon, Surrey, on Feb. 2, 1859. Both his father and maternal grandfather were sea captains, and much of his childhood was spent on the Pacific. After teaching for four years in New South Wales, he qualified for the medical profession at St. Thomas's Hospital, London. For a short time he engaged in general practice but very soon abandoned it for literary and scientific work. The more popular researches of the Freudian school have to a considerable extent overshadowed the methods of Ellis, in which more emphasis is laid on biology and less on clinical experience. In the last century, moreover, the extension of his fame beyond medical circles was impeded by the repugnance aroused in the ordinary reader by the subject matter of his studies. Only of late has it become possible to adjudge his work without prejudicial heat.

Yet Ellis has the unusual advantage of being able to expound his scientific theories in a clear and often beautiful style. The patience of a Darwin is combined with the literary brilliance of a Huxley; even when he is unable to convince he is sure to amuse; and, especially in his occasional writings, he brings to the totality of human experience a generous sympathy, a sharp intelligence and a daring wit. Whatever his studies had been, he would certainly have won a reputation as a literary artist.

His works include: *Studies in Psychology of Sex* (6 vols., 1898–1910); *Affirmations* (1898); *The World of Dreams* (1911); *Impressions and Comments* (3 series, 1914–24); the *Dance of Life* (1923); *Germinal,* trans. from the Fr. of Emile Zola (1925); *Sonnets, with Folk Songs from the Spanish* (Boston, 1925); *Man and Woman* (6th ed., 1926); *The New Spirit* (4th ed., Boston, 1926); *A Study of British Genius* (1927). *See* also: D. Isaac Goldberg, *Havelock Ellis: a Biographical and Critical Survey* (1926).

ELLIS, ROBINSON (1834–1913), English classical scholar, was born at Barming, Kent. He was Latin reader at Oxford from 1883 till 1893 when he became professor. His most important work was his *Commentary on Catullus* (1876, new ed. 1889), which aroused much criticism. He also translated the poems (1871) in the metres of the originals. His other works include *Noctes Manilianae,* dissertations on the *Astronomica,* with emendations (1891); editions of Avianus (1887), Velleius Paterculus (1898) and the Christian poet Orientius (1888), vol. xvi. of the Vienna *Corpus Scriptorum Ecclesiasticorum,* the *Ibis* of Ovid (1881), the *Aetna* of the younger Lucilius (1901), *Appendix Vergiliana* (an edition of the minor poems) (1908), and Ovid's *Amores* (1912).

ELLIS, WILLIAM (1794–1872), English Nonconformist missionary, was born in London on Aug. 29, 1794. His boyhood and youth were spent at Wisbech, where he worked as a market-gardener. He was sent by the London Missionary Society to the South Sea Islands in Jan. 1816, and remained in Polynesia, occupying various stations in succession, until 1824. Ellis improved the condition of the people. He acclimatized many species of tropical fruits and plants, and set up and worked the first printing press in the South Seas. Ellis was for some years a travelling agent of the London Missionary Society and was its foreign secretary 1832–39. He paid three visits to Madagascar (1853–57), inquiring into the prospects for resuming the work that had been suspended by Queen Ranavolona's hostility. A further visit was paid in 1863. Ellis wrote accounts of all his travels, and Southey praised (in the *Quarterly Review*) his *Polynesian Researches* (2 vols., 1829). He died on June 25, 1872.

ELLISTON, ROBERT WILLIAM (1774–1831), English actor, was born in London on April 7, 1774, and died there on July 8, 1831. He played first of all at Bath, later at Drury Lane, of which he was lessee from 1819 to 1826. From that time to his death he was lessee of the Surrey theatre.

ELLORA, a village of India, in the native state of Hyderabad, near the city of Daulatabad, famous for its rock temples. The caves differ from those of Ajanta in being excavated in the sloping sides of a hill and not in a nearly perpendicular cliff. They extend along the face of the hill for a mile and a quarter, and are divided into three distinct series, the Buddhist, the Brahmanical and the Jain, and are arranged almost chronologically. The most splendid is the Kailas, which is not a mere interior chamber but a model of a complete Dravidian temple, the rock having been cut away externally as well as internally. First the great sunken court was hewn out of the solid trap-rock of the hillside, leaving the rock mass of the temple wholly detached in a cloistered court, save that a rock bridge once connected the upper storey of the temple with the upper row of galleried chambers surrounding three sides of the court. Colossal elephants and obelisks stand on either side of the open mandapam, or pavilion, containing the sacred bull; and beyond rises the monolithic Dravidian temple to Siva, 90 ft. in height, hollowed into vestibule, chamber and image-cells, all lavishly carved. The temple was made under Krishna I., Rashtrakuta, king of Malkhed in 760–783.

ELLORE, a town of British India, in the Kistna district of Madras, on the East Coast railway, 303 m. from Madras. Pop. (1921) 45,062. The canal systems of the Godavari and the Kistna deltas meet here. There are carpet and hosiery manufactures, cotton, rice, jute and oil mills, cotton ginning and pressing factories, a tannery, saltpetre works, and an extensive trade in grain and rice. There is an important high school. Ellore was formerly a military station, and the capital of the Northern Circars. At Pedda Vegi to the north of it are extensive ruins, believed to be remains of the Buddhist kingdom of Vengi. From these the Mohammedans, after the conquest of the district in 1470, obtained material for building a fort at Ellore.

ELLSWORTH, OLIVER (1745–1807), American statesman and jurist, was born at Windsor, Conn., on April 29, 1745. He studied at Yale and Princeton, graduating from the latter in 1766, studied theology for a year, then law, and began to practise at Hartford in 1771. He achieved extraordinary success at the bar, amassing what was for his day a large fortune. From 1773 to 1775 he represented the town of Windsor in the general assembly of Connecticut. In 1779 he again sat in the assembly, this time representing Hartford. From 1777 to 1783 he was a member of the Continental Congress. From 1780 to 1785 he was a member of the governor's council of Connecticut, and from 1785 to 1789 he was a judge of the State superior court. In 1787, with Roger Sherman and William Samuel Johnson, he was one of Connecticut's delegates to the Constitutional Convention at Philadelphia. When disagreement seemed inevitable on the question of representation, he, with Roger Sherman, proposed what is known as the "Connecticut compromise," by which the Federal legislature was made to consist of two houses, the upper having equal representation from each State, the lower being chosen on the basis of population. From 1789 to 1796 he was one of the first senators from Connecticut under the new constitution. In the Senate he was looked upon as President Washington's personal spokesman and as the leader of the Administration Party. His most important service to his country was in connection with the establishment of the Federal judiciary. As chairman of the committee having the matter in charge, he drafted the bill by the enactment of which the system of Federal courts, almost as it is to-day, was established. By President Washington's appointment he became chief justice of the Supreme Court of the United States in March, 1796, and in 1799 President John Adams sent him, with William Vans Murray (1762–1803) and William R. Davie (1756–1820), to negotiate a new treaty with France. It was largely through the influence of Ellsworth, who took the principal part in the negotiations, that Napoleon consented to a convention, Sept. 30, 1800, which provided for freedom of commerce between the two nations. Failing health compelled him in 1800 to resign the chief-justiceship. He died in Windsor on November 27, 1807.

See W. G. Brown's *Oliver Ellsworth* (1905), an excellent biography. There is also an appreciative account of Ellsworth's life and work in H. C. Lodge's *A Fighting Frigate and Other Essays and Addresses* (1902), which contains in an appendix an interesting letter by Senator George F. Hoar concerning Ellsworth's work in the Constitutional Convention.

ELLWANGEN, a town of Germany in the republic of Württemberg, on the Jagst. Pop. (1925) 5,653. The Benedictine abbey of Ellwangen is said to have been founded in 764, but there is no record of it before 814. In 1460 the abbey was converted, with the consent of Pope Pius II., into a *Ritterstift* (college or institution for noble pensioners) under a secular provost. The town of Ellwangen, which grew up round the abbey and received the status of a town about the middle of the 14th century, was until 1803 the capital of the provostship, when this passed to Württemberg. It is situated between two hills, one crowned by the castle of Hohen-Ellwangen, built in 1354 and now used as an agricultural college, and the other, the Schönenberg, by the pilgrimage church of Our Lady of Loreto. The Stiftskirche, the old abbey church, a Romanesque building dating from 1124 and the Gothic St. Wolfgangskirche are the chief churches. The industries include making of parchment covers, of envelopes, of wooden hafts and handles for tools, etc., and tanneries. There are also a wool-market and a horse-market which is famous.

ELLWOOD, THOMAS (1639–1714), English author, was born at Crowell, Oxfordshire. His family moved to London while he was still young, and he met a Quaker family named Pennington, and himself became a Quaker. They introduced him to Milton, to whom he went every afternoon as Latin reader, and about whom his autobiography contains much information. His visits to Milton were interrupted by imprisonments for Quakerism. His story that after reading the ms. of *Paradise Lost* he suggested the idea of *Paradise Regained* seems improbable (*see* the chapter on Milton in *Cambridge History of English Literature* vol. vii.). Ellwood wrote polemical works in defence of Quakerism such as *Forgery No Christianity* (1674) and *The Foundation of Tithes Shaken* (1678); also some poems, including a *Davideis* in five books.

See *The History of the Life of Thomas Ellwood; written by his own hand* (1714); F. A. Budge, *Thomas Ellwood and other Worthies* (1891); A. K. Brown, *Thomas Ellwood, the Friend of Milton* (1910).

ELLWOOD CITY, a borough of Lawrence county, Pa., U.S.A., on the Connequessing river, 36m. N.W. of Pittsburgh. It is served by the Baltimore and Ohio, the Buffalo, Rochester and Pittsburgh, the Pennsylvania and the Pittsburgh and Lake Erie railways. The population in 1920 was 8,958 (21% foreign-born white), and was estimated locally at 15,000 in 1928. It is a manufacturing centre, making steel, brass, bronze, brick and other products characteristic of the Pittsburgh industrial district. The town was founded in 1889 as a summer resort, and was incorporated as a borough in 1892.

ELM, the popular name for the trees and shrubs constituting the genus *Ulmus*, of the family Ulmaceae. The genus contains 18 species widely distributed throughout the north temperate zone and also found in the mountains of the tropics.

The common European elm, *U. campestris*, a doubtful native of England, is found throughout a great part of Europe, north Africa and Asia Minor, whence it ranges east to north Asia and Japan. It grows in woods and hedge-rows, especially in southern Britain, and on almost all soils, attaining a height of 60 to 100, and occasionally 150 ft. The branches are numerous, spreading and often pendulous at the extremities; the bark is rugged; the leaves ovate, rough, doubly serrate, and, as in other species of *Ulmus*, unequal at the base. The flowers are small, numerous, in purplish-brown tufts, and each with a fringed basal bract; the bell-shaped calyx surrounds four free stamens; the pistil bears two spreading hairy styles. They appear before the leaves in March and April. The seed-vessels are green, membranous, one-seeded and deeply cleft. The first 10 years the tree usually reaches a height of 25 to 30 ft. The wood, at first brownish white, becomes later brown with a greenish shade. It is close-grained, free from knots, without apparent medullary rays, hard and tough, but will not take a polish. All parts of the trunk, including the sapwood, are available in carpentry. The wood has considerable transverse strength, does not crack when once seasoned, and is remarkably durable under water, or if kept quite dry. Elm wood is used for keels and bilge-planks, the blocks and dead-eyes of rigging, ships' pumps, coffins, wheels, furniture, carved and turned articles, and for general carpenters' work. For ornamental purposes elm trees are frequently planted, and in avenues, are highly effective. In Italy, as in ancient times, it is still customary to train the vine upon the elm. The cork-barked elm, *U. campestris*, var. *suberosa*, is distinguished chiefly by the thick deeply fissured bark with which its branches are covered. There are numerous cultivated forms differing in size and shape of leaf, and manner of growth.

ENGLISH ELM, SHOWING TWIG BEARING FLOWERS; THESE COME OUT BEFORE THE LEAVES, WHICH ARE ASYMMETRICAL
A. Cluster of flowers
B. Single flower showing toothed external envelope, stamens and forked stigma
C. Cluster of fruits (achenes)

The Scotch or wych elm, *U. montana*, is indigenous to Great Britain and is the common elm in the north; it usually attains a height of about 50 ft., but among tall-growing trees may reach 120 ft. It has drooping branches, smoother and thinner bark, larger and more tapering leaves, and a far less deeply notched seed-vessel than *U. campestris*. The wood is tough and hard when properly seasoned, and, being very flexible when steamed, is well adapted for boat-building. Branches of the wych elm were formerly manufactured into bows, and if forked were employed as divining-rods. The weeping elm is a variety of this species. The Dutch or sand elm is very similar to the wych elm, but produces inferior timber.

In North America there are six native species of elm, all occurring east of the Rocky Mountains, and chiefly in the southern United States. Of these the most widely distributed is the American or white elm (*U. americana*), which ranges from Newfoundland to the Great Lakes and the eastern base of the Rocky Mountains in Alberta south to Florida and Texas. This handsome tree is the largest American elm, sometimes attaining a height of 100 ft. or 120 ft., with a trunk diameter of 6 ft. to 11 ft., often enlarged by great buttresses at the base. It sometimes rises as a straight undivided shaft, 60 ft. to 80 ft. in height, before dividing into short spreading branches. Usually it separates at a height of 30 ft. or less into numerous upright limbs which gradually spread to form an inversely conical rounded head of long, slender, graceful branches, frequently 100 ft. and occasionally 150 ft. in diameter. In size, vigor and gracefulness it is fully equal to the European elm (*U. campestris*) and, like it, is extensively planted for shade and ornament in the northern States and adjacent Canada, especially in New England where it is a characteristic tree of streets and parks. A famous elm on Boston common, supposed to have been in existence before the settlement of Massachusetts, measured 22 ft. in circumference at the time of its destruction by a storm in 1876.

The red or slippery elm (*U. fulva*) is common in rich soil from Quebec to South Dakota and south to Florida and Texas. It grows 60 ft. to 70 ft. high and 1 ft. to 2 ft. in trunk diameter, with stiff branches, rough leaves and thick, fragrant, mucilaginous bark, much used in spring for chewing by small boys and employed in medicine as a demulcent. Less common are the rock or cork elm (*U. racemosa*) of the northern States and adjacent Canada, a large tree with corky bark, and the much smaller winged or Wahoo elm (*U. alata*), likewise with corky bark, found in the southern States. The southern red elm (*U. serotina*) and the cedar elm (*U. crassifolia*), both of limited range in the southern States, differ from the other American elms in flowering in autumn instead of in spring. When of sufficient size, all American elms are of value as timber trees. The total cut of elm lumber, according to the U.S. census of 1925, was 190,630,000 bd.ft., mostly white elm, one-half of which was produced in the States of Michigan and Wisconsin.

ELMACIN, GEORGE (*c.* 1223–1274), author of a history of the Saracens, which extends from the time of Mohammed to the year 1118 of our era. He was a Christian of Egypt, where he was born; is known in the east as Ibn-Amid; and after holding an official position under the sultans of Egypt, died at Damascus. His history is principally occupied with the affairs of the Saracen empire, but it contains passages which relate to the Eastern Christians. It was published in Arabic and Latin at Leiden in 1625. The Latin version is a translation by Erpenius, under the title, *Historia saracenica*, and from this a French translation was made by Wattier as *L'Histoire mahométane* (Paris, 1657).

ELMALI ("apple-town"), a kaza in the vilayet of Adalia in Asia Minor, the present administrative centre of most of the ancient Lycia. It lies about 25 m. inland, at the head of a long upland valley (5,000 ft.) inhabited by direct descendants of the ancient Lycians, who have preserved a distinctive facial type. Pop. (1927) 16,126. The district is agricultural.

ELMAN, MISCHA (1891–   ), violinist, was born at Stalnoje, Russia, on Jan. 20, 1891, received his first musical teaching from his father, a schoolmaster, but subsequently studied under Fidelmann at Odessa, and later under Auer at St. Petersburg (Leningrad), where as a Jew he was enabled to reside only by virtue of a special dispensation granted by the Tsar. Recognition of his extraordinary talents was immediate, not only in Russia, but elsewhere throughout Europe. He paid his first visit to London in 1905 and to the United States in 1908. During the World War he was relieved of the obligation of military service to which as a Russian subject he would otherwise have been liable. During recent years he has practised his art chiefly in America, where he has made many tours, and after his marriage in San Francisco in 1925 he became a permanent resident of New York.

His first name is a diminutive of Michael.

ELMHAM, THOMAS (d. *c.* 1420), English chronicler, was probably born at North Elmham in Norfolk. He became a Benedictine monk at Canterbury, and then, joining the Cluniacs, was prior of Lenton Abbey, near Nottingham; he was chaplain

to Henry V., and was present at Agincourt. Elmham wrote a history of the monastery of St. Augustine at Canterbury (edit. C. Hardwick, Rolls Series, 1858); and a *Liber metricus de Henrico V.* (edit. C. A. Cole, in *Memorials of Henry V.* 1858). It is probable that he wrote the famous *Gesta Henrici Quinti*, which is the best authority for the life of Henry V. from his accession to 1416. This work, often referred to as the "chaplain's life," and thought by some to have been written by Jean de Bordin, has been published for the English Historical Society by B. Williams (1850). Elmham, however, did not write the *Vita et Gesta Henrici V.*, which was attributed to him by T. Hearne and others.

See C. L. Kingsford, *Henry V.* (1901).

ELMHURST, a city of Du Page county, Ill., U.S.A., 16m. W. of Chicago. It is served by the Chicago and North Western, the Chicago, Aurora and Elgin, the Chicago Great Western, and the Illinois Central railways, and has a commercial airport, Eagle field. The population was 4,594 in 1920, and was estimated locally at 15,000 in 1928. Stone quarries, woodworking and steel mills, brick-yards, and greenhouses constitute the leading industries of the city. It is the seat of Elmhurst college for men (Evangelical) established in 1871. Elmhurst was incorporated as a city in 1900.

ELMINA, a town on the Gold Coast, British West Africa, in 5° 4′ N., 1° 20′ W. and about 8 m. W. of Cape Coast. Pop. (1921) under 5,000. Facing the Atlantic on a rocky peninsula is Fort St. George, considered the finest fort on the Guinea coast. It is built square with high walls, and has accommodation for 200 soldiers. On the land side were formerly two moats, cut in the rock on which the castle stands. The houses in the native quarter are mostly built of stone, that material being plentiful in the vicinity.

Elmina was the first permanent European settlement on the Gold Coast. Diogo d'Azambuja was sent by John II. of Portugal to the coast for that purpose and he began, in 1481, the building of a fortress called São Jorge da Mina. One of the officers with d'Azambuja was Bartholemew Diaz. It was on this occasion or very soon afterward that Christopher Columbus visited the Guinea coast; his son records his father's statement "I have stayed in the Portuguese fortress of St. George of the Mine." It took 80 years before the fort was completed. Another defensive work is Fort St. Jago, built in 1666, which is behind the town and at some distance from the coast. (In the latter half of the 19th century it was converted into a prison.) Elmina was captured by the Dutch in 1637, and ceded to them by treaty in 1640. They made it the chief port for trade with Ashanti. With the other Dutch possessions on the Guinea coast, it was transferred to Great Britain in April 1872. The king of Ashanti, claiming to be ground landlord, objected to its transfer, and the result was the Ashanti war of 1873–1874. Up to the close of the 19th century the greatest output of gold from this coast came from Elmina. The annual export is said to have been nearly £3,000,000 in the early years of the 18th century, but the figure is probably exaggerated. The building of the railway from Sekondi to the gold mines took the trade away. Prempeh, the ex-king of Ashanti, was detained in the castle (1896) until his removal to the Seychelles. (*See* ASHANTI: *History,* and GOLD COAST: *History.*)

ELMIRA, a city of southern New York, U.S.A., on the Chemung river, at an altitude of 850ft.; the county seat of Chemung county. It is served by the Erie, the Lackawanna, the Lehigh Valley and the Pennsylvania railways. The population was 45,393 in 1920 (88% native white) and was estimated locally at over 54,000 in 1928. The city lies on both sides of the river, and is surrounded by wooded hills. The area is 7·4 sq.m. It is the seat of Elmira college for women (1853). The New York State reformatory for first offenders (men) 16–30 years of age, opened at Elmira in 1876 under the direction of Zebulon R. Brockway (1827–1920), has had a great influence on correctional methods in the United States and abroad. Its distinctive features are the indeterminate sentence; a strict regimen of physical training, work and academic instruction, and a marking system. Elmira is an important railway centre, and has extensive manufactures, including fire-engines, milk bottles, iron and steel bridges, valves and Bendix drives (for automobiles). The aggregate factory output in 1925 was valued at $35,107,555. Bank clearings in 1926 amounted to $52,400,000, and the assessed valuation of property was $47,093,426.

The site of Elmira was the intersection point of several important Indian trails, and there were several Indian villages in the vicinity. The first log cabin was built in 1778. The village was incorporated in 1815 as Newtown, and reincorporated in 1828 as Elmira. In 1832 the Chemung canal connected it with Lake Seneca, and in 1849 the first railroad (the Erie) reached it. It was chartered as a city in 1864, and by 1870 had a population of 15,863. Near the site of Elmira on Aug. 29, 1779, was fought the battle of Newtown, in which Gen. John Sullivan decisively defeated a force of Indians and Tories under Sir John Johnson and Joseph Brant. In 1861 a military camp was established here, and in 1864–65 there was a camp for Confederate prisoners. Mark Twain had a summer home ("Quarry Farm") near Elmira, and his grave is in Woodlawn Cemetery.

EL MORRO, a national reservation, technically known as a national monument, in the western part of Valencia county, New Mexico, U.S.A., and about 10 m. east of the Zuni Indian reservation. The reservation (240 ac. in area) was established to preserve an enormous sandstone rock eroded in the form of a castle, upon which inscriptions were placed by early Spanish explorers. It also contains cliff-dweller ruins of great historic, scenic and ethnologic interest.

ELMSHORN, a town of Germany, in the Prussian province of Schleswig-Holstein, on the Krückau, 19 m. by rail N.W. from Altona. Pop. (1925) 15,231. Its industries include weaving, dyeing, brewing, iron-founding and the manufacture of leather goods, boots and shoes, margarine, sugar and machines. There is a considerable shipping trade.

ELMSLEY, PETER (1773–1825), English classical scholar, was educated at Winchester and Christ Church, Oxford. He travelled extensively in France and Italy, and spent the winter of 1818 in examining the mss. in the Laurentian library at Florence. In 1823 he was appointed principal of St. Alban's Hall, Oxford, and Camden professor of ancient history. A man of extensive learning, Elmsley was considered the best ecclesiastical scholar in England; but he is chiefly famous for his work on the mss. of the Greek tragedians. He edited the *Acharnians* of Aristophanes and several of the plays and scholia of Sophocles and Euripides. He was the first to recognize the importance of the Laurentian mss. (*see* Sandys, *Hist. of Class. Schol.* iii., 1908).

ELNE, a town of south-western France in the department of Pyrénées-Orientales, 10 m. S.S.E. of Perpignan by rail. Pop. (1926) 3,172. The hill on which it stands, once washed by the sea, now over 3 m. distant, overlooks the plain of Roussillon. Elne, the ancient *Illiberis,* was named *Helena* by the emperor Constantine in memory of his mother. Hannibal encamped under its walls on his march to Rome in 218 B.C. The emperor Constans was assassinated there in A.D. 350. The town often changed hands between its capture by the Moors in the 8th century and its capitulation in 1641 to the troops of Louis XIII. From the 6th century till 1602 the town was the seat of a bishopric, which was transferred to Perpignan. The cathedral of St. Eulalie, early 12th century Romanesque, has a beautiful cloister in the same style, with interesting sculptures and three early Christian sarcophagi. There are remains of the ancient ramparts flanked by towers. Trade is in wine.

EL OBEID, chief town of the mudiria (province) of Kordofan, Anglo-Egyptian Sudan, and 230 m. S.W. by S. of Khartum; pop. about 17,000. It is situated about 2,000 ft. above the sea, at the northern foot of Jebel Kordofan, in 13° 11′ N. and 30° 14′ E. It is an important trade centre, and the southern terminus of the Sudan Government railway; the chief articles of commerce being gum, ivory, cattle and ostrich feathers. A considerable part of the trade of Darfur with Egypt passes through El Obeid.

El Obeid was garrisoned by the Egyptians on their conquest of Kordofan in 1821. In September 1882 the town was assaulted by the troops of the mahdi, to whom it capitulated on Jan. 17, 1883. During the Mahdia the city was destroyed and deserted, and when Kordofan passed, in 1899, into the possession of the Anglo-

Egyptian authorities nothing was left of El Obeid but a part of the old government offices. A new town was laid out in squares, the mudiria repaired and barracks built.

ELOI (Eligius), **SAINT** (588–659), bishop of Noyon and apostle of the Belgians and Frisians, was born at Cadillac, near Limoges. Trained as a goldsmith, he became coiner to Clotaire II., king of the Franks, and treasurer to his successor Dagobert. Both kings entrusted him with important artistic works, and though he was amassing great wealth, Eloi resolved to become a priest. He retired to a monastery, but in 640 was raised to the bishopric of Noyon. He made frequent missionary excursions to the Low Countries, where he founded many monasteries and churches. He died on Dec. 1, 659. St. Eloi is the patron saint of goldsmiths.

Migne's *Patrol. Lat.* vol. 87 contains his *Homilies* and his life written by his friend St. Ouen (Audoenus), French trans. Paris, 1626, 1847 and 1870. *See* also P. Parsy, *S. Eloi* (1907), and Potthast, *Bibliotheca hist. med. aevi* (Berlin, 1896).

ELONGATION, strictly, "lengthening"; in astronomy, the apparent angular distance of a heavenly body from its centre of motion, as seen from the earth; designating especially the angular distance of the planet Mercury or Venus from the sun, or the apparent angle between a satellite and its primary. The greatest elongation of Venus is about 45°; that of Mercury generally ranges between 18° and 27°.

EL PASO, a city in the extreme western corner of Texas, U.S.A., on the Rio Grande, opposite the Mexican city Juárez; a port of entry, the county seat of El Paso county and the largest city on the Mexican border. It is on Federal highways 80 and 366; and is served by the Santa Fe, the Southern Pacific, the Texas and Pacific and the Mexican North-western railways, and the National railways of Mexico. The population was 77,560 in 1920, of whom 30,769 were natives of Mexico; and was estimated by the census bureau at 113,500 in 1928. The city occupies 13 sq.m. on the mesas at the foot of Mt. Franklin, at an altitude of 3,752 ft., with the Organ, Hueco, Sacramento, Guadalupe and Sierra Madre ranges in the background. The climate is mild and dry, particularly beneficial in cases of pulmonary disease. In the architecture of both public and private buildings the early Spanish influence is apparent. The Mexican section is picturesque with gay shops and its adobe houses, many of which are over 100 years old. In 1916–17, following a survey of health and housing made for the chamber of commerce, 2,000 unsanitary *jacales* (community dwellings) in the Mexican quarter were razed by the health department. The court-house (completed 1917) contains a public auditorium seating 6,000, the county jail (on the top floor) and a roof garden. A fine high school and stadium was completed in 1915, at a cost of $1,000,000. The parks, covering 679 ac., include one of 43 ac. which is a memorial to the men who fell in the World War. A scenic driveway around Mt. Franklin (built in 1919) gives fine views of the city and the valley. A city plan is being developed in accordance with recommendations of a commission appointed in 1922. The assessed valuation of property in 1927 was $102,150,000.

Climate, cattle, copper and cotton are the chief foundations of El Paso's economic life. There are several large sanatoria in or near the city, including the William Beaumont general hospital of the U.S. army at Ft. Bliss; and it is estimated that 100,000 tourists visit the city annually for health or pleasure. The stockyards handle 400,000 head of live stock, and the trade in leather, hides, wool, mohair and fertilizers amounts to $70,000,000 annually. The principal manufacturing industry is the smelting of copper and lead ores from Mexico, New Mexico and Arizona, in one of the largest custom smelters of the world (just outside the city limits), which handles 500,000 tons of ore in a year. The output of the factories within the city was valued at $42,350,000 in 1927. There are extensive car shops, two meat-packing plants, a large cement plant, one of the largest wooden box factories in the country, many diversified smaller plants; and the introduction of cotton-growing in the valley has brought in the associated manufacturing industries—cotton gins and compresses, cotton-seed oil mills and a textile factory with over 5,000 spindles. El Paso is the centre of the Rio Grande reclamation project of 180,000 ac., for which water is supplied from the Elephant Butte reservoir (completed 1916). By 1927 about 138,000 ac. was under cultivation, producing crops valued at $12,000,000, of which about two-thirds was cotton. For this rapidly developing agricultural valley, and for the wide expanse of mining, grazing and lumbering regions within its trade territory, El Paso is the commercial and financial centre. A branch of the Federal Reserve Bank of Dallas is located here. Debits to individual accounts in the city's banks aggregated $387,393,501 in 1927. The foreign commerce of the El Paso customs district in 1927 amounted to $9,347,268 in imports and $11,572,709 in exports.

El Paso is the seat of the College of Mines of the University of Texas (established 1914), and of several private boarding-schools. Three miles north-east is Ft. Bliss, a cavalry post with a reservation of 2 sq.m., a garrison of 5,000 to 10,000 men, an Air Corps flying field (Biggs field), and a large base hospital. Juarez, across the river, is a colourful ancient city, with the oldest Spanish mission in this part of the country, Nuestra Señora de Guadalupe (established 1659). At Ysleta, 10 m. S.E., live the survivors of an ancient tribe of Pueblo Indians, and here is the second oldest mission of the region, Nuestra Señora del Carmen (established 1682).

The first European visitor of record to the site of El Paso was Cabeza de Vaca, in 1536. Other pioneers stopped here from time to time, and in 1659 the first permanent settlement was made. It was won from Mexico in the Texas War of Liberation in 1836. Before the Mexican War it was known as Ponce de Leon Ranch; afterwards, for a time, as Franklin. The name El Paso was adopted when the new town was plotted in 1858, perpetuating the Spanish phrase (*El paso del norte*) for the pass to the north formed here where the river breaks through the mountains. The city was incorporated in 1873, and in 1880 the population was 736. In 1881 four railroads rushed in their tracks in a race for the most favourable terminal site, and by 1890 the population was 10,338. In the next decade it increased 54%; between 1900 and 1910, 147%; between 1910 and 1920, 98%. A commission form of government was adopted in 1907.

ELPHINSTONE, MOUNTSTUART (1779–1859), Indian statesman and historian, fourth son of the 11th Baron Elphinstone in the peerage of Scotland, was born in 1779. Having received an appointment in the civil service of the East India Company, of which one of his uncles was a director, he reached Calcutta in the beginning of 1796. He was appointed in 1801 assistant to the British resident at Poona, at the court of the peshwa, the most powerful of the Mahratta princes. Here he obtained his first opportunity of distinction, being attached in the capacity of diplomatist to the mission of Sir Arthur Wellesley to the Mahrattas. When, on the failure of negotiations, war broke out, Elphinstone, though a civilian, acted as virtual aide-de-camp to General Wellesley and was present at the battle of Assaye. In 1804, when the war closed, he was appointed British resident at Nagpur. In 1808 he was appointed the first British envoy to the court of Kabul, with the object of securing a friendly alliance with the Afghans; but this proved of little value, because Shah Shuja was driven from the throne by his brother before it could be ratified. Elphinstone was appointed in 1810 to the difficult post of resident at Poona. The difficulty arose from the general complication of Mahratta politics, and especially from the weak and treacherous character of the peshwa. While the mask of friendship was kept up Elphinstone carried out a policy of vigilant quiescence with admirable tact and patience; in 1817 the mask was thrown aside and the peshwa ventured to declare war. The success of the British troops was chiefly owing to his assuming the command at an important crisis during the battle of Kirkee.

The peshwa being driven from his throne, his territories were annexed to the British dominions, and Elphinstone was nominated commissioner to administer them. He discharged the responsible task with rare judgment and ability. In 1819 he was appointed lieutenant-governor of Bombay and held this post till 1827, his principal achievement being the compilation of the "Elphinstone code." He may fairly be regarded as the founder

of the system of State education in India, and he did much towards the promotion of native education. His connection with the Bombay presidency was commemorated in the endowment of the Elphinstone college by the native communities, and in the erection of a marble statue by the European inhabitants.

Returning to England in 1829, after an interval of two years' travel, Elphinstone retained in his retirement an important influence on public affairs. He twice refused the offer of the governor-generalship of India. He wrote *Account of the Kingdom of Cabul and its Dependencies in Persia and India* (1815). His history of India (1841), embraces the Hindu and Mohammedan periods, and is still a work of high authority. He also published *The Rise of British Power in the East* (1858). He died on Nov. 20, 1859.

See J. S. Cotton, *Mountstuart Elphinstone* ("Rulers of India" series) (1892); T. E. Colebrooke, *Life of Mountstuart Elphinstone* (1884); and G. W. Forrest, *Official Writings of Mountstuart Elphinstone* (1884).

ELPHINSTONE, WILLIAM (1431–1514), Scottish statesman and prelate, founder of the University of Aberdeen, was born in Glasgow, and educated at the university. He was ordained priest, becoming rector of St. Michael's church, Trongate, Glasgow, in 1465. Four years later he went to continue his studies at the University of Paris, where he became reader in canon law, and then, proceeding to Orleans, became lecturer in the university there. Before 1474 he had returned to Scotland, and was made rector of the university, and official of the see of Glasgow. Elphinstone was made bishop of Ross in 1481. He was a member of the Scots parliament, and was sent by King James III. on diplomatic errands to Louis XI. of France, and to Edward IV. of England; in 1483 he was appointed bishop of Aberdeen, although his consecration was delayed for four years; and he was sent on missions to England, both before and after the death of Richard III. in 1485. Early in 1488 the bishop was made lord high chancellor, but on the king's death in the following June he vacated this office, and retired to Aberdeen. James IV. sent him on missions to the kings of England and France, and the German king, Maximilian I. He was made keeper of the privy seal in 1492.

The bishop's concluding years were mainly spent in the foundation of the University of Aberdeen. The papal bull for this purpose was obtained in 1494, and the royal charter which made old Aberdeen the seat of a university is dated 1498. A small endowment was provided by the king, and the university, modelled on that of Paris and intended principally to be a school of law, soon became the most famous and popular of the Scots seats of learning, a result which was largely due to the wide experience and ripe wisdom of Elphinstone and of his friend, Hector Boece, the first rector. The building of the college of the Holy Virgin in Nativity, now King's college, was completed in 1506, and the bishop also rebuilt the choir of his cathedral, and built a bridge over the Dee. Elphinstone opposed the policy of hostility towards England which led to the disaster at Flodden in Sept. 1513, and died in Edinburgh on Oct. 25, 1514. He was partly responsible for the introduction of printing into Scotland, and for the production of the *Breviarium Aberdonense*. He may have written some of the lives in this collection, and gathered together materials concerning the history of Scotland; but he did not, as some have thought, continue the *Scotichronicon*, nor did he write the *Lives of Scottish Saints*.

See Hector Boece, *Murthlacensium et Aberdonensium episcoporum vitae*, ed. and trans. J. Moir (Aberdeen, 1894); *Fasti Aberdonenses*, ed. C. Innes (Aberdeen, 1854); and A. Gardyne, *Theatre of Scottish Worthies and Lyf of W. Elphinston*, ed. D. Laing (Aberdeen, 1878).

EL RENO, a city of Oklahoma, U.S.A., near the North Fork of the Canadian river, 28m. W. by N. of Oklahoma City; the county seat of Canadian county. It is on Federal highways 66 and 81, and is served by the Oklahoma (electric) and the Rock Island railways. The population was 7,737 in 1920 (91% native white), and was estimated locally at 10,500 in 1928. It lies on a rolling prairie, 1,360ft. above sea-level, and is an important shipping point for poultry, cream and other farm products. Its industries include railroad shops, flour mills, washing machine and incubator factories. There is a Government boarding-school for Indians at Concho, 6m. north-west. Ft. Reno Remount Depot is 4m. north-west. A military post was established at Ft. Reno in 1876. The city was founded in 1889 and incorporated in 1892.

ELSFLETH, a maritime town of Germany, in the republic of Oldenburg, in a fertile district at the confluence of the Hunte with the Weser. Pop. (1925) 3,317. It is one of the centres of the North Sea herring fishery and has shipbuilding yards.

ELSHEIMER, ADAM (1579–1620), German painter, born in Frankfurt, son of Anthony Elsheimer, a well-to-do tailor. He studied under Phipp Uffenbach at Frankfurt. His early work betrays Flemish influence. The manner in which his figure subjects are staged in landscapes seems to suggest a connection with followers of Gillis van Coninxloo at Frankenthal. ("John the Baptist Preaching" in the Munich Pinakothek.) In 1598 Elsheimer worked under Johann Rottenhamer in Munich, and here first met with the classic tradition ("St. Paul at Lystra" in the Staedel at Frankfurt; and the "Fall of Troy" in Munich). He left for Italy soon afterwards, stayed in Venice, and in 1600 proceeded to Rome where he remained to the end of his life. He seems to have been successful for he enjoyed the patronage of church dignitaries and the friendship of Paul Brill and Rubens. His Italian pictures with landscapes, taken from the surroundings of Rome, were composed in the classic style, the colour being inspired by Venice. Pictures of this period are in most of the important museums of Europe. In his last works he seems to have followed Caravaggio both as regards the dark tonality and the treatment of figures. ("Ceres" at the Prado, Madrid.) At the end of his life he suffered from extreme dejection; but Sandrart's story of his debts is not altogether trustworthy.

He has been called one of the founders of modern landscape painting; for he broke away from tradition in his careful and minute study of nature. His pictures are small in size and are painted on copper. His backgrounds display distant views; the horizon is placed low in the picture. His interpretation is romantic. Moreover, in the rendering of light and atmosphere, he was a precursor of Rembrandt. ("Philemon and Baucis" at Dresden.) His influence on art was considerable. Many of his works were engraved by his friend and pupil, Hendrik Goudt. Pieter Lastman and Jan Pynas were among his followers. The Staedel at Frankfurt has a large collection of his drawings; he also executed some engravings.

See J. v. Sandrart, *Die Deutsche Akademie* (1768); David Passavant, "Adam Elsheimer," *Archiv für Frankfurts Geschichte und Kunst*, Heft 4, 8 (1847); W. v. Bode, "Adam Elsheimer," *Jahrbuch der Kgl. Pr. Kunstsammlungen I.* (1880).

ELSINORE (Dan. *Helsingør*), a seaport of Denmark on the east coast of the island of Zealand, 28 m. N. of Copenhagen. Pop. (1928) 15,100. It stands at the narrowest part of the Sound, opposite the Swedish town of Helsingborg, 3 m. distant. Railway communication is maintained by means of a train ferry. Helsingør received town privileges in 1425. In 1522 it was taken and burnt by Lübeck, but in 1535 was retaken by Christian II. It is celebrated as the Elsinore of Shakespeare's *Hamlet*. On a tongue of land east of the town stands the castle of Kronborg built by Frederick II. in Dutch Renaissance style and extensively restored by Christian IV. after a fire in 1637. It was taken by the Swedes in 1658, but returned to the Danes in 1660. It is now mainly used as a maritime museum. The town possesses also the Carmelite monastery St. Maria church, the old hospital, Marienlyst castle and the ruins of the castle of Eric of Pommern. Helsingør has an important shipyard, which, after the abolition of the Sound dues, has helped to bring prosperity to the town.

ELSSLER, FANNY (1810–1884), Austrian dancer, was born in Vienna on June 23, 1810. From her earliest years she was trained for the ballet, and made her appearance at the Kärntner-Thor theatre in Vienna before she was seven. She usually danced with her sister Theresa, who was two years her senior; and, after some years' experience together in Vienna, the two went in 1827 to Naples. Their success there—to which Fanny contributed most—led to an engagement in Berlin in 1830. This was the beginning of a series of triumphs for Fanny's personal beauty and

skill in dancing. After captivating all hearts in Berlin and Vienna, and inspiring the statesman Friedrich von Gentz (*q.v.*) with a remarkable passion, she visited London, where she received much kindness at the hands of Mr. and Mrs. Grote, who practically adopted the little girl who was born three months after the mother's arrival in England. In Sept. 1834 Fanny Elssler appeared at the Opera in Paris, a step to which she looked forward with much misgiving on account of Taglioni's supremacy there. The result was the temporary eclipse of Taglioni, who, although a finer artist, could not compete with the newcomer's personal charm. In her performance of the Spanish *cachucha* Fanny Elssler outshone all rivals. In 1845, having amassed a fortune from tours in America and in Europe, she retired from the stage and settled near Hamburg. Her sister Theresa contracted a morganatic marriage with Prince Adalbert of Prussia, and was ennobled under the title of Baroness von Barnim. Fanny Elssler died at Vienna on Nov. 27, 1884. Theresa was left a widow in 1873, and died on Nov. 19, 1878.

See A. Ehrharde, *Une vie de danseuse: Fanny Elssler* (1909).

ELSTER, the name of two rivers of Germany. (1) The Schwarze (Black) Elster rises in the Lausitz range, on the southern border of Saxony, flows north and north-west, and after a course of 112 m. enters the Elbe a little above Wittenberg. It is a sluggish stream, winding its way through sandy soil and frequently along a divided channel. (2) The Weisse (White) Elster rises in the north-western corner of Bohemia, a little north of Eger, cuts through the old hard rocks of the Vogtland in a deep and picturesque valley, passing Plauen and Greiz. Further downstream, round Gera and Zeitz, the scenery changes and for the rest of its course it meanders through lower and often sandy land. Above Leipzig it receives its chief tributary, the Pleisse. At Leipzig it divides, the main stream turning north-west and entering the Saale a little above Halle; the other arm, the Luppe, flowing parallel to the main stream and south of it enters the Saale below Merseburg. Total length, 121 m.; total descent, 1,286 ft.

ELSTER, a spa, in the republic of Saxony, on the Weisse Elster, close to the Bohemian frontier on the railway Plauen-Eger, and 20 m. S. of the former, has industries of lace-making and weaving, and a population of (1925) 3,368. The mineral springs, saline-chalybeate, have been supplemented by baths of various kinds, and these, together with natural attractions make the place a summer resort.

ELSWICK, ward, west parliamentary division, Newcastle-upon-Tyne, England. It contains the great ordnance and naval works of Sir W. G. Armstrong, Mitchell and Co., Elswick park.

EL TEB, a halting-place in the Anglo-Egyptian Sudan near the coast of the Red sea, 9 m. S.W. of the port of Trinkitat on the road to Tokar. There were two battles there in 1884. In the first, on Feb. 4, a heterogenous Egyptian force under Baker Pasha was destroyed by the Sudanese tribesmen under Osman Digna. In the second, on Feb. 29, a British force under General Graham partially avenged this disaster. For an account *see* EGYPT AND SUDAN CAMPAIGNS IN 1882–1899.

ELTON, CHARLES ISAAC (1839–1900), English lawyer and antiquary, was born at Southampton on Dec. 6, 1839. He was educated at Cheltenham and Balliol college, Oxford, and was called to the bar at Lincoln's inn in 1865. He had a large conveyancing practice, took silk in 1885, and was M.P. for West Somerset. He died at Whitestaunton on April 23, 1900. His literary work, like his practice, was mainly concerned with old English real property law and custom. His best-known works are *The Tenures of Kent* (1867); *Treatise on Commons and Waste Lands* (1868); *Law of Copyholds* (1874); *Origins of English History* (1882).

See a memoir by Andrew Lang, prefixed to Elton's *William Shakespeare, his Family and Friends* (1904).

ELTVILLE or **ELFELD,** town of Germany, in the Prussian province of Hesse-Nassau, on the right bank of the Rhine, 5 m. S.W. from Wiesbaden, on the railway Frankfort-on-Main-Cologne. Pop. (1925) 4,101. Eltville (originally *Adeldvile*, Lat. *Altavilla*), is first mentioned in a record of the year 882, was given by the emperor Otto I. to the archbishops of Mainz, and received town rights in 1331. In 1465 Gutenberg set up his press at Eltville, and several examples of printed books issued by this press survive, the earliest being the *Vocabularium Latino-Teutonicum*, first printed in 1467. Eltville was once capital of the Rheingau and has ruins of a feudal castle, and a monument to Gutenberg. It has a considerable trade in the wines of the district and two manufactories of sparkling wines.

ELTZ, a small river of Germany, a left bank tributary of the Mosel. It rises in the lower Devonian rocks of the Eifel range, and, after a swift course of 5 m., joins the latter river at Moselkern, nearly 20 m. S.W. of Coblenz. Just above its confluence stands the romantic castle of Eltz, crowning a rocky summit 900 ft. high, and famous as being one of the best preserved mediaeval strongholds of Germany. It is the ancestral seat of the counts of Eltz and contains numerous antiquities.

See Roth, *Geschichte der Herren und Grafen zu Eltz* (2 vols., 1889–90).

ELVAS, an episcopal city and frontier fortress of Portugal, 170 m. E. of Lisbon, and 10 m. W. of the Spanish fortress of Badajoz. Pop. (1920) 11,747. Elvas is finely situated on a hill 5 m. N.W. of the river Guadiana. It is defended by seven bastions and the two forts of Santa Luzia and Nossa Senhora da Graça. A fine aqueduct, 4 m. long, was begun early in the 15th century and completed in 1622. The surrounding lowlands are very fertile, and Elvas is celebrated for its excellent olives and plums. The fortress of Campo Maior, 10 m. N.E., is famous for its siege by the French and relief by the British under Marshal Beresford in 1811.

Elvas is the Roman *Alpesa* or *Helvas*, the Moorish *Balesh*, the Spanish *Yelves*. It was wrested from the Moors by Alphonso VIII. of Castile in 1166; but was temporarily recaptured before its final occupation by the Portuguese in 1226. It twice withstood sieges by the Spanish, in 1658 and 1711. The French under Marshal Junot took it in March 1808, but evacuated it in August, after the conclusion of the convention of Cintra (*see* PENINSULAR WAR).

ELVEY, SIR GEORGE JOB (1816–1893), English organist and composer, was born at Canterbury on March 27, 1816. He studied at the Royal Academy of Music under Cipriani Potter and Dr. Crotch. In 1834 he gained the Gresham prize medal for his anthem, "Bow down thine ear," and in 1835 was appointed organist of St. George's chapel, Windsor, a post which he filled for 47 years, retiring in 1882. He took the degree of Mus. B. at Oxford in 1838 and in 1840 that of Mus. D. Elvey, who was knighted in 1871, died at Windlesham in Surrey on Dec. 9, 1893. His works, which are nearly all for the Church, include two oratorios, a great number of anthems and services, and some pieces for the organ. A memoir of him, by his widow, was published in 1894.

ELVIRA, SYNOD OF, an ecclesiastical synod held in Spain, probably in 305 or 306, at Elvira, not far from or perhaps (Dale) identical with the modern Granada. There 19 bishops and 24 presbyters, from all parts of Spain, but chiefly from the south, assembled, probably at the instigation of Hosius of Córdova, with a view to restoring order and discipline in the Church. The 81 canons which were adopted reflect with considerable fulness the internal life and external relations of the Spanish Church of the 4th century. The social environment of Christians may be inferred from the canons prohibiting marriage and other intercourse with Jews, pagans and heretics, closing the offices of *flamen* and *duumvir* to Christians, forbidding all contact with idolatry and likewise participation in pagan festivals and public games. The state of morals is mirrored in the canons denouncing prevalent vices. The canons respecting the clergy exhibit the clergy as already a special class with peculiar privileges, a more exacting moral standard, heavier penalties for delinquency. The bishop has acquired control of the sacraments, presbyters and deacons acting only under his orders; the episcopate appears as a unit, bishops being bound to respect one another's disciplinary decrees. The following canons are worthy of special note: xxiii., enjoining celibacy upon all clerics and all who minister at the altar (the most ancient canon of

celibacy); xxxvi., forbidding pictures in churches; xxxviii., permitting lay baptism under certain conditions; and liii., forbidding one bishop to restore a person excommunicated by another.

See Dale, *The Synod of Elvira* (1882), an exhaustive monograph; Hennecke, art. "Elvira" in Herzog-Hauck, *Realencyklopädie;* Hefele, *History of Church Councils,* Eng. tr. vol. i., pp. 131 ff.; and the reference to the Spanish Church in the General Church Histories.

EL WAD, a town in the Southern region of Algeria, 125 m. in a straight line S.S.E. of Biskra, and 190 m. W. by S. of Gabes. Pop. 8,621. El Wad is one of the most interesting places in Algeria. It is surrounded by huge hollows containing noble palm groves (67,000 palms); and beyond these on every side stretches the limitless desert with its great billows of sand, the encroachments of which on the oasis are only held at bay by ceaseless toil. The town itself consists of a mass of one-storeyed stone houses, each surmounted by a little dome, clustering round the market-place with its mosque and minaret. El Wad oasis is one of a group known collectively as the Suf. Five miles N.W. is Kuinine (pop. 3,938) and 6 m. farther N.W. Guemar (pop. 6,798), an ancient fortified town noted for its manufacture of carpets with an important *Zaouïa* or convent of the order of Tidjaniya. Linen weaving is carried on extensively in the Suf. Administratively El Wad is the capital of an annex to the territory of Tuggurt.

ELWES, GERVASE CARY (1866–1921), English tenor singer, son of Valentine Cary Elwes, of Billing Hall, Northants., was born at Billing on Nov. 15, 1866, and educated at the Oratory school, Edgbaston, and Christ church, Oxford. In 1889 he married Lady Winefride Feilding, daughter of the 8th earl of Denbigh. In 1891 he was appointed to the diplomatic service, and became honorary attaché at Munich, and later at Vienna and Brussels. He studied music under Mandyczevski in Vienna, under Demest in Brussels, and under Bouhy in Paris. He entered the musical profession while still in the diplomatic service, which he finally abandoned in 1895. He made his first public appearances in 1903 at the Westmorland festival and at a concert of the Handel Society in London, subsequently achieving wide popularity at the hands of the most critical public. He took part in over 150 performances of *The Dream of Gerontius,* with which his name became indissolubly associated, while he excelled also in the interpretation of Bach. He was killed in an accident at Boston on Jan. 12, 1921, while on tour in the United States. The exceptional quality of the esteem which he enjoyed at the hands of the public was subsequently attested by the medallion erected to his memory in the Queen's hall, London.

ELWOOD, a city of Madison county, Ind., U.S.A., 48m. N.E. of Indianapolis. It is served by the Nickel Plate, the Union Traction of Indiana and the Pennsylvania railways. The population was 10,790 in 1920 (96% native white) and was estimated locally at 12,000 in 1928. It is an important shipping point for grain and live stock, and has large tinplate works, glass factories and various other manufacturing industries. The total factory output in 1925 was valued at $14,620,498. Elwood was settled in 1852 and was chartered as a city in 1891. Until 1869 it was known as Quincy. Between 1890 and 1900 the population grew from 2,284 to 12,950, following the discovery of natural gas. Failure of the supply in 1903 caused a temporary decline in the amount of manufacturing and consequently in the population.

ELY, a cathedral city and market-town, in the administrative and parliamentary county of the Isle of Ely, England, 14¾ m. N.N.E. of Cambridge by the L.N.E. railway. Pop. of urban district (1921) 7,690. Ely stands on a considerable eminence on the west bank of the Ouse, in the Isle which rises above the surrounding fens. The cathedral, towering above the town, is a landmark far over the surrounding level. It is at the junction of a network of railway branch lines (to Huntingdon, Peterborough, Norwich and Newmarket), and by means of the Ouse and the Cam has a wide inland navigation. The soil in the vicinity is fertile and market-gardening is carried on. A large beet sugar factory was erected in 1925. St. Mary's parish church ranges in style from Norman to Perpendicular, but in the main represents the Early English structure of Bishop Eustace (d. 1215). Holy Trinity church, formerly the Lady chapel of the cathedral (*see* below), on the north side of the choir, has served as a parish church since 1566. The public buildings include the shire hall and the corn exchange. The grammar school, known as The King's school, founded by Henry VIII. in 1541, and now enlarged and modernized, includes the old gatehouse of the monastery, known as the Porta, and the chapel built by Prior John de Cranden (1321–1341). Among the other educational institutions are Needham's school, founded in 1734, the Cathedral Choristers' school (1862) and a theological college founded in 1876 and opened in 1881.

History.—The architectural foundations of the present cathedral were laid by its first Norman abbot, Simeon (1081–94). But the reputation of Ely had been established long before, when Etheldreda (Aethelthryth), daughter of Anna, king of East Anglia, and wife to Ecgfrith, king of Northumbria, founded a religious house here, in all probability a mixed community, in 673, becoming its first abbess, and giving the whole Isle of Ely to the foundation. In 870 the monastery was destroyed by the Danes, as were also the neighbouring foundations at Soham, Thorney, Crowland and Peterborough. It remained in ruins till 970, when Aethelwold, bishop of Winchester, founded a new Benedictine monastery here. King Edgar in 970 endowed the monks with the former possessions of the convent, and also granted them the secular causes of certain lands within and without the marshes and certain other privileges and revenues in the province of Grantecestre. The wealth and importance of Ely rose, and its abbots held the post of chancellors of the king's court alternately with the abbots of Glastonbury and of St. Augustine's, Canterbury. In the struggle against William the Conqueror, of which Hereward "the Wake" was the hero, Ely again became a scene of contest. Finally, in 1071, the monks agreed to surrender the Isle of Ely to the king on condition of the confirmation of all the possessions and privileges held by them in the time of Edward the Confessor. Abbot Simeon, who now began the reconstruction of the church, was related to William and brother to Walkelin, first Norman bishop of Winchester. Under Abbot Richard (1100–07) the translation from the Saxon church of the bodies of St. Etheldreda and the two abbesses who had followed her, and their enshrinement in the new edifice, took place. The feast of St. Etheldreda, or St. Awdrey as she was generally called, was the occasion every year for a large fair at which "trifling objects" were sold to pilgrims by way of souvenirs; whence the word "tawdry," a contraction of St. Awdrey. In 1108–09 the Isle of Ely, most of Cambridgeshire and the abbeys of Thorney and Cetricht were separated from the diocese of Lincoln, and converted into a new diocese, Ely being the seat of the bishopric. After the Dissolution of the monasteries Henry VIII. converted the conventual church into a cathedral (1541), granting to the dean and chapter the cathedral with its revenues and precincts. The diocese was enlarged in 1837 and 1839, and until recently covered nearly the whole of Cambridgeshire, Huntingdonshire and Bedfordshire, part of Suffolk, and small portions of Essex, Norfolk, Northamptonshire, Hertfordshire and Buckinghamshire. But in 1913 Bedfordshire was transferred to St. Albans and West Suffolk to St. Edmundsbury and Ipswich, and the diocese now includes Cambridgeshire, Huntingdonshire and certain parishes in Norfolk.

Cathedral.—The cathedral is a cruciform structure, 537 ft. long and 190 ft. across the great transepts (exterior measurements). A relic of the Saxon foundation is preserved in the cross of St. Osyth (*c.* 670), and a pre-Norman window is preserved in the triforium, which was unearthed near the cathedral. The nave, which is Norman throughout, is 208 ft. in length, 72 ft. 9 in. to the top of the walls, and 77 ft. 3 in. broad, including the aisles. The great western tower and the transept, which are also Norman, were completed in the 12th century. The tower, which is 215 ft. high, is surmounted by a Decorated octagon with partly detached side turrets, and underwent alteration and strengthening in the Perpendicular period. The Galilee, or western porch, by which the cathedral is entered, is the work of Bishop Eustace, and is a perfect example of Early English style. In 1322 the Norman central tower, erected by Abbot Simeon, fell. Alan of Walsing-

ham, sacrist of the church, designed its restoration (1322–28) in the form of the present Decorated octagon, a beautiful and unique conception. Instead of the ordinary four-arched central crossing, an octagon is formed at the crossing, the arches of the nave aisles and choir aisles being set obliquely, while upon the ribbed vaulting of wood above it rose the lofty lantern, octagonal also, with its angles set opposite those of the octagon below. The total height is 170 ft. 7 in. Under Bishop John of Hotham (1316–37) the Lady chapel, a beautiful example of Decorated work, was also begun in 1321. It is attributed to John Wisbech, a monk, working under Alan de Walsingham, and was completed in 1349. Of the seven bays of the choir the four easternmost (as well as the two beyond forming the retrochoir) had been built by Bishop Hugh of Northwold (d. 1254), and the three western bays which were destroyed by the fall of the tower were now rebuilt by Bishop Hotham and completed by his successors. The earlier portion is a superb example of Early English work, while the later is perhaps the best example of pure Decorated in England; the elaborate choir stalls are attributed to Richard de Saxmundham (1338–46). The Perpendicular style is represented by the windows of the aisles and certain other details. There are also some splendid tombs, like that of Bishop John Redman (d. 1505), and the two chapels of Bishop John Alcock (d. 1500) and Bishop Nicolas West (d. 1534) in this style. Among earlier monuments the canopied tomb of Bishop William de Luda (1290–98) and the finely-carved effigy of Bishop Northwold (1254) are notable. Between 1845 and the end of the century, the cathedral underwent restoration. The work included the erection of the modern reredos and choir-screen, both designed by Sir G. Scott, and the painting of the nave roof by Styleman le Strange (d. 1862), who was succeeded by Gambier Parry. Parry also richly ornamented the octagon and lantern in the style of the 14th century.

Of the remains of the monastic buildings. mention has been made of the Ely "Porta" and of Prior John's beautiful chapel. But many of the remains, the bulk of which are incorporated in the deanery and canons' and other residences, are of much earlier date, such as the Norman undercroft of the prior's hall and the notable transitional Norman chancel of the infirmary chapel. The remnants of the cloisters show a 15th century reconstruction; but the prior's and monks' doorways from the cloisters into the cathedral are decorated late Norman. The bishop's palace has towers erected by Bishop Alcock. In the muniment room of the chapter is preserved the *liber Eliensis*, a history of the monastery by the monk known as Thomas of Ely (d. *c.* 1174), of which the first part, which extends to the year 960, contains a life of St. Etheldreda, while the second is continued to the year 1107.

Ely, which according to Bede (*Hist. eccl.* iv. 19) derives its name from the quantity of eels in the waters about it, was a borough by prescription at least as early as the reign of William the Conqueror. For a long time the abbot, and afterwards the bishop, had almost absolute power in the town. The bailiff who governed the town was chosen by the bishop until 1850, when a local board was appointed. Richard I. granted the bishop of Ely a fair there, and in 1319–20 Bishop Hotham received license to hold a fair. The markets are claimed by an undated charter by the bishop, who also continues to hold the fairs. In 1295 Ely sent two members to parliament, but was not represented thereafter. It was constituted an urban district under the Local Government act of 1894.

See C. W. Stubbs, *Ely Cathedral* (1897); *Victoria County History, Cambridgeshire.*

ELY, a city of St. Louis county, Minnesota, U.S.A., on Long lake, 117m. N. by E. of Duluth, at the entrance to the Superior national forest. It is served by the Duluth and Iron Range railroad, and is the northern terminus for motor travel in the "Arrowhead country." The population was 4,902 in 1920 (37% foreign-born white) and was estimated locally at 6,000 in 1928. There are five underground iron mines, employing 1,500 men the year round. The city is a centre for tourists and sportsmen, situated as it is in the midst of millions of acres of primeval wilderness and surrounded by a network of beautiful lakes. It is headquarters of the Superior national forest service. Ely was settled about 1886 and was incorporated in 1891.

ELYOT, SIR THOMAS (*c.* 1490–1546), English diplomat and scholar. His father was Sir Richard Elyot, judge of common pleas. The date and place of his birth are not known. Nor is the place of his education; both St. Mary Hall, Oxford and Jesus college, Cambridge, claim him, while he himself says in the preface to his *Dictionary* that he was educated at home, and from the age of 12 taught himself. In 1511 he accompanied his father as clerk of assize on the western circuit; later Wolsey made him clerk to the Privy Council. In 1530 he was displaced and knighted. He married Margaret Barrow, a student in the "school" of Sir Thomas More, and his known friendship with More was afterwards a bar to his advancement. In 1531 he produced the *Boke named the Governour,* dedicated to Henry VIII. The same year he was sent to the court of Charles V. to further Henry's divorce from Catherine of Aragon, and to attempt to catch William Tyndale. He served on the commission on the monasteries and on a second embassy to Charles V. in 1535. In 1542 he represented Cambridge in parliament. He died at Carleton in Cambridgeshire on March 26, 1546. The *Boke named the Governour* is a treatise on moral philosophy for the education of princes, and contains many classical quotations. It was very popular. He acknowledges his debt to Erasmus's *Institutio Principis Christiani,* but does not mention Patrizzi's *De regno et regis institutione,* on which his book was modelled. In 1534 he produced the *Castell of Helth,* a popular treatise on medicine, ridiculed by the doctors, but widely read. His *Latin Dictionary,* the first complete one in English, was finished in 1535, and edited and enlarged by Thomas Cooper, Bishop of Winchester, in 1548.

Elyot's translations include:—The *Doctrinal of Princes* (1534), from Isocrates; *Cyprianus, A Swete and Devoute Sermon of Holy Saynt Ciprian of the Mortalitie of Man* (1534); *Rules of a Christian Life* (1534), from Pico della Mirandola; *The Education or Bringing up of Children* (*c.* 1535), from Plutarch; and *Howe one may take Profite of his Enymes* (1535), from the same author is generally attributed to him. He also wrote: *The Knowledge which maketh a Wise Man* and *Pasquyll the Playne* (1533); *The Bankette of Sapience* (1534), a collection of moral sayings; *Preservative agaynste Deth* (1545), which contains many quotations from the Fathers; *Defence of Good Women* (1545). His *Image of Governance, compiled of the Actes and Sentences notable of the most noble Emperor Alexander Severus* (1540) professed to be a translation from a Greek MS. of the emperor's secretary Encolpius (or Eucolpius, as Elyot calls him), which had been lent him by a gentleman of Naples, called Pudericus, who asked to have it back before the translation was complete. In these circumstances Elyot, as he asserts in his preface, supplied the other maxims from different sources. He was violently assailed by Humphrey Hody and later by William Wotton for putting forward a pseudo-translation; but Mr. H. H. S. Croft has discovered that there was a Neapolitan gentleman at that time bearing the name of Poderico, or, Latinized, Pudericus, with whom Elyot may well have been acquainted. Roger Ascham mentions his *De rebus memorabilibus Angliae;* and Webbe quotes a few lines of a lost translation of the *Ars poëtica* of Horace.

A learned edition of the *Governour* (2 vols., 1880), by H. H. S. Croft, contains, besides copious notes, a valuable glossary of 16th century English words.

ELYRIA, a city of northern Ohio, U.S.A., on the Black river, 8m. S. of Lake Erie and 25m. W.S.W. of Cleveland; the county seat of Lorain county. It is on Federal highway 20, and is served by the Baltimore and Ohio and the New York Central railways, and by inter-urban trolley and motor bus lines. The population was 20,474 in 1920 (16% foreign-born white); was estimated locally at 27,000 in 1928, and 32,000 including immediate suburbs. The city has an altitude of 720ft., and lies at the junction of the east and west branches of the Black river, each of which falls about 40ft. here, in beautiful Cascade park. There are numerous and varied manufactures, including laces, furnaces and heaters, invalid chairs, alloys, hosiery, motors, fishing tackle, chemicals, portable cranes, golf balls, automobiles, cold rolled steel, seamless pipe, marine and stationary engines and radios. The aggregate output in 1925 was valued at $26,187,397. In 1816 Heman Ely of Massachusetts visited land owned by his father in the Connecticut Western Reserve, and contracted for the building of a grist-mill, a saw-mill and a cabin. He returned the next March with skilled workmen and labourers, took possession of the cabin, and called the town Elyria. It was selected for the county seat in 1823, and was chartered as a city in 1892.

ELYSIUM or the Elysian Plain, or Fields, the pre-Hellenic paradise, identified by the Greeks with their own Islands of the Blessed. In Homer (*Od.*, iv. 563) the Elysian Plain is a land of perfect happiness, ruled by Rhadamanthys, at the end of the earth, on the banks of the river Oceanus. Much the same description is given by Hesiod (*Works and Days*, 167) of the Islands of the Blessed. In Pindar (*Olymp.*, ii. 67 et seq., frags. 129, 130, von Christ) Rhadamanthys and Cronus (who is mentioned also in a doubtfully genuine line in Hesiod, *loc. cit.*) rule there. In the earlier authors, only those specially favoured of the gods enter; and, in Homer, they are carried there body and soul and made immortal. In Hesiod it is already a place for the blessed dead, and, from Pindar on, entrance is gained by a righteous life, a conception partly at least due to Orphism. In later authors, such as Virgil (*Aen.*, vi. 637 et seq.), Elysium is part of Hades; originally it has nothing to do with it.

For fuller discussion, *see* especially E. Rohde, *Psyche*, and A. Dieterich, *Nekyia*.

ELZE, KARL (1821–1889), German scholar and Shakespearian critic, was born at Dessau on May 22, 1821. He studied at Leipzig and in 1875 was appointed extraordinary, and in 1876 ordinary professor of English philology at the university of Halle, where he died on Jan. 21, 1889. Elze's most important works are: his biographies of Walter Scott, Byron and Shakespeare; *Abhandlungen zu Shakespeare* (Eng. trans. by D. Schmitz, *Essays on Shakespeare*, 1874), and the excellent treatise, *Notes on Elizabethan Dramatists with conjectural emendations of the text* (3 vols., Halle, 1880–86, new ed. 1889).

ELZEVIR, the name of a family of Dutch printers belonging to the 17th century. The original name was Elsevier, or Elzevier, and their French editions mostly retain this name; but in their Latin editions the name is spelt Elzeverius, gradually corrupted in English into Elzevir. Louis (1540–1617), who first made the name Elzevir famous, was born at Louvain. Compelled in 1580, on account of his Protestantism and his adherence to the cause of the insurgent provinces, to leave his native country, he established himself as bookbinder and bookseller in Leyden. The earliest Elzevir is now known to be *Drusii Ebraicarum quaestionum ac responsionum libri duo*, produced in 1583. In all he published about 150 works. Of his five sons, Matthieu, Louis, Gilles, Joost and Bonaventure, Bonaventure, who was born in 1583, is the most celebrated. He began business as a printer in 1608, and in 1626 took into partnership Abraham, a son of Matthieu. Both died in 1652. The fame of the Elzevir editions rests chiefly on the works issued by this firm. Their Greek and Hebrew impressions are inferior to those of the Aldi and the Estiennes, but their small editions in 12mo, 16mo and 24mo, for elegance of design, neatness, clearness and regularity of type and beauty of paper, cannot be surpassed. Especially may be mentioned the two editions of the New Testament in Greek, published in 1624 and 1633, of which the latter is the more beautiful and the more sought after; the *Psalterium Davidis*, 1653; *Virgilii opera*, 1636; *Terentii comediae*, 1635; but the works which gave their press its chief celebrity are their collection of French authors on history and politics in 24mo, known under the name of the *Petites Républiques*, and their series of Latin, French and Italian classics in small 12mo. Jean, son of Abraham, born in 1622, had since 1647 been in partnership with his father and uncle, and when they died Daniel, son of Bonaventure, born in 1626, joined him. Their partnership did not last more than two years, and after its dissolution Jean carried on the business alone till his death in 1661. In 1654 Daniel joined his cousin Louis (the third of that name), who had established a printing press at Amsterdam in 1638. From 1655 to 1666 they published a series of Latin classics in 8vo, *cum notis variorum; Cicero* in 4to; the *Etymologicon linguae Latinae;* and a magnificent *Corpus juris civilis* in folio, 2 vols., 1663. The last representatives of the Elzevir printers were Peter, grandson of Joost, and Abraham, son of the first Abraham, who from 1681 to 1712 was university printer at Leyden.

Some of the Elzevir editions bear no other typographical mark than simply the words *Apud Elzeverios*, or *Ex officina Elseveriana*, under the *rubrique* of the town. But the majority bear one of their special devices, four of which are recognized as in common use. Louis Elzevir, the founder of the family, usually adopted the arms of the United Provinces, an eagle on a cippus holding in its claws a sheaf of seven arrows, with the motto *Concordia res parvae crescunt*. About 1620 the Leyden Elzevirs adopted a device, known as "the solitary," and consisting of an elm tree, a fruitful vine and a man alone, with a motto *Non solus*. They also used another device, a palm tree with the motto, *Assurgo pressa*. The Elzevirs of Amsterdam used for their principal device a figure of Minerva with owl, shield and olive tree, and the motto, *Ne extra oleas*. The earliest productions of the Elzevir press are marked with an angel bearing a book and a scythe, and various other devices occur. When the Elzevirs did not wish to put their name to their works they generally marked them with a sphere, but the fact that a work printed in the 17th century bears this mark is no proof that it is theirs. The total number of works of all kinds which came from the presses of the Elzevirs is given by Willems as 1,608; there have also been many forgeries.

See Alphonse Willems, *Les Elzévier* (1880), with a history of the Elzevir family and their printing establishments, a chronological list and detailed description of all works printed by them, their various typographical marks, and a plate illustrating the types used by them; Kelchner, *Catalogus librorum officinae Elsevirianae* (1880); Frick, *Die Elzevirschen Republiken* (Halle, 1892); Berghman, *Etudes sur la bibliographie Elzévirienne* (Stockholm, 1885), and *Nouvelles études, etc.* (*ib.* 1897). *See* H. B. Copinger, *The Elzevier Press* (London, 1927).

EMANATION, in philosophy and theology, the name of one of the three chief theories of the relation between God and men—the One and the Many, the Universal and the Particular (Lat. *emanatio*, from *e-*, out, *manare*, to flow). This theory has been propounded in many forms, but the central idea is that the universe of individuals consists of the "outpourings" of the ultimate divine essence. That essence is not only all-inclusive, but absolutely perfect, while the "emanated" individuals degenerate in proportion to their distance from the essence. The existence of evil in opposition to the perfect goodness of God, as thus explained, need not be attributed to God's agency, inasmuch as the whole emanation-process is governed by necessary laws, which may be compared to those of the physical universe. The doctrine of emanation is thus to be distinguished from the cosmogonic theory of Judaism and Christianity, which explains human existence as due to a single creative act of a moral agent. The God of Judaism and Christianity is essentially a *person* in close *personal* relation to his creatures; emanation is the denial of personality both for God and for man. The emanation theory is to be contrasted, on the other hand, with the theory of evolution. The two theories are alike in so far as both recognize the existence of individuals as due to a necessary process of differentiation and a scale of existence. They differ, however, fundamentally in this respect, that, whereas evolution regards the process as from the lower towards the higher, emanation regards it as from the higher to the lower.

There is considerable superficial similarity between evolution and emanation, especially in their formal statements. The process of evolution from the indeterminate to the determinate is often expressed as a progress from the universal to the particular. Thus the primordial matter assumed by the early Greek physicists may be said to be the universal substance out of which particular things arise. The doctrine of emanation also regards the world as a process of particularization. Yet the resemblance is more apparent than real. The universal is, as Herbert Spencer remarked, a subjective idea, and the general forms, existing *ante res*, which play so prominent a part in Greek and mediaeval philosophy, do not in the least correspond to the homogeneous matter of the physical evolutionists. The one process is a logical operation, the other a physical. The theory of emanation, which had its source in certain moral and religious ideas, aims first of all at explaining the origin of mental or spiritual existence as an effluence from the divine and absolute spirit. In the next place, it seeks to account for the general laws of the world, for the universal forms of existence, as ideas which emanate from the Deity. By some it was developed into a complete philosophy

of the world, in which matter itself is viewed as the lowest emanation from the absolute. In this form it stands in sharp antithesis to the doctrine of evolution, both because the former views the world of particular things and events as essentially unreal and illusory, and because the latter, so far as it goes, looks on matter as eternal, and seeks to explain the general forms of things as we perceive them by help of simpler assumptions. In certain theories known as doctrines of emanation, only mental existence is referred to the absolute source, while matter is viewed as eternal and distinct from the divine nature. In this form the doctrine of emanation approaches certain forms of the evolution theory (*see* EVOLUTION).

The doctrine of emanation is correctly described as of oriental origin. It appears in various forms in Indian philosophy, and is the characteristically oriental element in syncretic systems like Neoplatonism and Gnosticism. None the less it is easy to find it in embryo in the speculations of the essentially European philosophers of Greece. Plato, whose philosophy was strongly opposed to the evolution theory, distinctly inclines to the emanation idea in his doctrine that each particular thing is what it is in virtue of a pre-existent idea, and that the particulars are the lowest in the scale of existence, at the head of, or above, which is the idea of the good. The view of Xenocrates is based on the same ideas. Or again, we may compare the Stoic doctrine of **ἀπόρροιαι** (literally "emanations") from the divine essence. It is, however, only in the last eclectic period of Greek philosophy that the emanation doctrine was definitely established in the doctrines, *e.g.*, of Plotinus.

See especially articles EVOLUTION, NEOPLATONISM, GNOSTICISM.

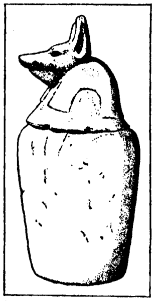
EMANUEL I. (Portuguese *Manoel*) (1469–1521), 14th king of Portugal, surnamed the "Great" and the "Happy" knight of the Garter and of the Golden Fleece, was the son of Duke Ferdinand of Vizeu and of Beatrice of Beja, grandchildren of John I. of Portugal. His reign (1495–1521) is noteworthy for Vasco da Gama's opening an all-sea route to India, Cabral's landing in Brazil, Corte-Real's voyage to Labrador, the exploration of the Indian seas and the opening of commercial relations with Persia and China. He also appointed Albuquerque viceroy of the Portuguese possessions in India. His intense religious zeal manifested itself in his persecutions of the Jews and in endeavours to promote a crusade against the Turks, in his missionary enterprise throughout his new possessions, and in his erection of 26 monasteries and two cathedrals, including the stately monastic church of the Jeronymos at Belem. He was married three times, to Isabella, daughter of Ferdinand and Isabella of Castile, to her sister Maria, and then to Leonora, sister of the emperor Charles V. By Maria he had two sons, John and Henry, both of whom became kings of Portugal.

The best authorities for the history of Emanuel's reign are the contemporary 16th century *Chronica d' el Rei D. Manoel,* by Damião de Goes, and *De rebus Emanuelis,* by J. Osorio. *El Rei D. Manoel,* by M. B. Branco (Lisbon, 1888), is a valuable but ill-arranged biography. *See* also the *Ordenações do S.R.D. Manoel* (Coimbra, 1797). For further bibliography *see* Barbosa Machado, *Bibliographica Lusitana,* vol. iii. pp. 161–166.

EMAUS, a borough of Lehigh county, Pa., U.S.A., on the Reading railroad, 6m. S. of Allentown. The population was 4,370 in 1920 (95% native white).

EMBALMING, the art of preserving dead bodies from decay. The custom of embalming had its origin in Egypt, probably as early as the 1st Dynasty. As practised by the Egyptians and other peoples of antiquity and by modern races of relatively low culture, embalming is usually spoken of as "mummification." The art was probably suggested by the natural preservation of bodies buried in predynastic times in the desert sands in Egypt. Bodies so inhumed survive to-day in a wonderful state of preservation owing to the total exclusion of air and moisture by contact with the sand. The adoption of more elaborate funerary offerings necessitated roomier graves, and bodies were thus no longer covered with sand but exposed to air and consequently decomposed. This led to the attempt to achieve by art that which unaided nature accomplished in simple sand-burials. Embalming in Egypt reached a high stage of development, its greatest elaboration being accomplished at the time of the 21st Dynasty (*see* MUMMY). The practice survived in Egypt until the Byzantine period, and throughout its long career the embalmers had two objects in view: the preservation of the body from decay and the perpetuation of the personal identity of the deceased. The motive was a belief in the physical survival of the dead.

Outside Egypt embalming has a wide geographical distribution, and in many places it has survived until recent times, although it is everywhere tending to disappear. The Guanches of the Canary Islands mummified their dead in a manner closely resembling that of the Egyptians, and there are traces of the custom, or debased survivals of it, in many parts of the African continent. In Indonesia, Australia, Melanesia, and Polynesia embalming in various forms has been practised principally for chiefs and persons of importance, the best preserved mummies being those of the Torres Straits Islands. In North, Central, and South America mummies have been found, many specimens having been discovered in ancient sites, particularly those of the Inca civilization.



BY COURTESY OF THE METROPOLITAN MUSEUM OF ART

EGYPTIAN CANOPIC JAR IN WHICH INTESTINES OF EMBALMED WERE PLACED

References to embalming occasionally occur in classical literature. Herodotus (ii. 85–88), Diodorus Siculus (i. 91), Plutarch (*De carn. esu* and *Sept. Sap. Conv.* xvi.), Porphyry (*De Abst.* iv. 10), Plato (*Phaedo* xxix.), Lucian (*De Luctu*), Strabo (xvi. 2, 45), Cicero (*Tuscul. Disp.* i.), and others, mention Egyptian embalming. Herodotus also mentions methods practiced by the Persians (i. 140), the Ethiopians (iii. 24) and the Scythians (iv. 71). Tacitus (*Annals,* xvi. 6) states that Nero's wife was embalmed "according to the manner of foreign kings"; Statius (*Silv.* iii. 2, 117) affirms that the body of Alexander the Great was embalmed with honey, and the same material was employed to conserve the corpse of Agesipolis I. during its conveyance to Sparta for burial, according to Emilius Probus and Cornelius Nepos. The early Christian writers inveigh against the custom of embalming as a pagan usage (*e.g.,* Augustine, *De Diversis,* xii. Serm. 120).

Embalming was occasionally practised in Europe during the middle ages. Thus in 1135 the body of Henry I. was embalmed by a method recalling that of the Egyptians: incisions were made in the body, the viscera removed, and aromatic substances were introduced into the vacant body-cavity. Although in the meantime embalming was often practised, it was not until the end of the 17th century that any real scientific research into the matter had been made. The methods of embalming devised by Ruysch of Amsterdam (1665–1717) and others, arose out of experiments made to discover a satisfactory means of preserving anatomical preparations. Numerous methods, each claiming perfection, were propounded during the 18th and 19th centuries: the substances used included essential oils, alcohol, camphor, pitch, salt, and corrosive sublimate. Gypsum was also used as a dehydrating agent.

Embalming is declining mainly owing to the rapid growth of cremation. Modern embalming is accomplished by the injection of drugs into the vascular system without removing any organs (*see* MUMMY).

EMBANKMENT. In engineering, generally, a mound or bank of earth, stone, or other material, usually narrow in comparison with its length, artificially raised above the prevailing level of the ground. Embankments may form parts of works or structures of varied character but usually serve for one or other of two main classes of purpose. On the one hand, they are used to preserve the level of railways (*q.v.*), roads, canals, and cause-

ways in cases where a valley or piece of low lying ground has to be crossed. In such circumstances they are commonly of earth suitably consolidated and drained. Embankments are also constructed for carrying railways and roads over marsh land or land liable to flooding, and, in some cases, over the shallow beds of lakes and seas: *e.g.*, the railway across the Great Salt Lake in Utah and that joining the mainland with the Florida Keys (*q.v.*). When formed on marsh land it is often necessary to make special provision to prevent or minimize sinking. A problem which frequently has to be considered by the railway engineer and the roadmaker is the relative economy of constructing an embankment or, its usual alternative, a viaduct.

On the other hand embankments are employed, in varied forms and circumstances, to stop or limit the flow of water, for instance: (a) For confining a river, canal, or other water course within fixed limits (*see* CANALS AND CANALIZED RIVERS; RIVER ENGINEERING; AQUEDUCT). (b) In fen or marsh lands to prevent flooding or to form the sides of drainage channels or ditches raised above the general level of the land. In the Fens (*q.v.*) they are known as "banks" and the men employed in constructing and maintaining them as "bankers." (c) On the sea coast or in estuaries for the purpose of coast protection (*q.v.*) and land reclamation, in some cases combined with a wall. Such embankments are sometimes referred to as sea-walls irrespective of their form. (d) For retaining water in a reservoir (*q.v.*) or for raising the water level of a lake when they are more usually described as "earth-dams" (*see* DAM).

Puddled clay, curtain walls of concrete, and steel sheet piling are frequently utilized in the construction of embankments when it is necessary to secure watertightness, and in most uses of embankments to limit or stop the flow of water some form of protection of the face of the work against erosion is required such as covering it with stone, slag, or concrete.

The word embankment has come to be used in particular instances for the mass of material, faced and supported by a stone or concrete wall, placed along the banks of a river where it passes through a city, whether to guard against floods or to gain additional space. Such is the Thames Embankment in London, which carries a broad roadway. In this sense an embankment is distinguished from a quay, though the structural form may be similar, the latter word being confined to places where ships are loaded and unloaded, thus differing from the French *quai* which is used both of embankments and quays, *e.g.*, the *Quais* along the Seine at Paris. In Holland (*q.v.*) the term *dike* is applied to any embankment designed to limit the flow of water. (N. G. G.)

EMBARGO may be either civil or hostile. Civil embargo is the restraint placed by a sovereign upon his own subjects, by prohibiting them or their vessels from leaving the realm. This measure was taken by the United States in retaliation for the Berlin and Milan Decrees of Napoleon of 1806 and 1807, and the British Orders in Council of 1807 and 1809, declaring interdiction of all intercourse with their respective subjects or the subjects of their allies on the part of neutrals. An embargo was consequently laid upon all American shipping by the president. Hostile embargo is the seizure and detention by the sovereign of one State of the subjects and property of another State with a view to obtain redress for some injury by exercising pressure on the latter State. If such seizure leads to war the embargo becomes retroactive, and the persons and property—usually merchant vessels and their crews—become tainted *ab initio* as enemy persons and property. In either case embargo is an act short of war. The seizure and detention of enemy ships lying in its ports by a belligerent on the outbreak of war is not within the meaning of the term.

See ANGARY; PACIFIC BLOCKADE; REPRISALS; RETORTION; WAR. (H. H. L. B.)

EMBASSY, the office of an ambassador, or, more generally, the mission on which an ambassador of one Power is sent to another, or the body of official personages attached to such a mission, whether temporary or permanent. The word is also used of the official residence of an ambassador. (*See* further AMBASSADOR, EXTERRITORIALITY, and DIPLOMACY.)

EMBER DAYS and **EMBER WEEKS,** the four seasons set apart by the Western Church for special prayer and fasting, and the ordination of clergy, known in the mediaeval Church as *quatuor tempora*, or *ieiunia quatuor temporum*. The Ember weeks are the complete weeks next following Holy Cross day (September 14), St. Lucy's day (December 13), the first Sunday in Lent and Whit Sunday. The Wednesdays, Fridays and Saturdays of these weeks are the Ember days distinctively, the following Sundays being the days of ordination. The derivation of the word from Anglo-Saxon *ymb-ren*, a circuit or revolution, is confirmed by the use of the word *imbren* in the acts of the Council of Aenham, A.D. 1009 ("ieiunia quatuor tempora quae *imbren* vocant"). It corresponds also with Pope Leo the Great's definition, "ieiunia ecclesiastica per totius anni circulum distributa."

The observance of the Ember days is confined to the Western Church, and had its origin as an ecclesiastical ordinance in Rome. They were probably at first merely the fasts preparatory to the three great festivals of Christmas, Easter and Pentecost. A fourth was subsequently added, for the sake of symmetry, to make them correspond with the four seasons, and they became known as the *ieiunium vernum, aestivum, autumnale* and *hiemale*. From Rome the Ember days gradually spread throughout Western Christendom, but neither in Gaul nor Spain do they seem to have been generally recognized much before the 8th century. Their introduction into Britain appears to have been earlier, dating from Augustine, A.D. 597, acting under the authority of Gregory the Great. Lack of uniformity led to the rule now observed being laid down under Pope Urban II. in A.D. 1095.

The present rule which fixes the ordination of clergy in the Ember weeks cannot be traced farther back than the time of Pope Gelasius, A.D. 492–496.

Church*, bk. iv. ch. vi. § 6, bk. xxi. ch. ii. §§ 1–7; Binterin, *Denkwürdigkeiten*, vol. v. part 2, pp. 133 ff.; Augusti, *Handbuch der christlich. Archäol.* vol. i. p. 465, iii. p. 486.

EMBEZZLEMENT, in English law, a form of theft, which is distinguished from the ordinary crime of larceny in two points:—(1) It is committed by a person who is in the position of clerk or servant to the owner of the property stolen; and (2) the property when stolen has been received from a third person and has not reached the possession of the master, the owner. The definition of embezzlement as a special form of theft arose out of the difficulties caused by the legal doctrine that to constitute larceny the property must be taken out of the possession of the owner. Servants and others were thus able to steal with impunity goods entrusted to them for their masters. A statute of Henry VIII. (1529) was passed to meet this case, which was not covered by the common law.

Other statutes have been passed from time to time, but the law now in force is the Larceny Act 1916, which by ss. 16 to 19 deals with this offence.

By that act every person who being a clerk or servant or person employed in the capacity of a clerk or servant fraudulently embezzles the whole or any part of any chattel, money or valuable security delivered to or received or taken into possession by him for or in the name or on the account of his master or employer: or being employed in the public service of the sovereign or in the police of any place whatsoever embezzles or in any manner fraudulently applies or disposes of for any purpose whatsoever except for the public service any chattel, money or valuable security entrusted to or received or taken into possession by him by virtue of his employment: or being appointed to any office or service by or under a local marine board fraudulently applies or disposes of any chattel, money or valuable security received by him for or on account of any local marine board or for or on account of any other public board or department, for his own use or any use or purpose other than that for which the same was received by him; or fraudulently withholds, retains, or keeps back the same, or any part thereof, contrary to any lawful directions, is guilty of felony and on conviction thereof liable to penal servitude for 14 years, and in the case of a clerk or servant, if a male under the age of 16 years, to be once privately whipped in addition to any other

punishment.

Again every person who, being an officer of the Post Office, steals or embezzles a postal packet in course of transmission by post shall be guilty of felony and on conviction thereof liable, if the postal packet contains any chattel, money or valuable security, to penal servitude for life: in all other cases to penal servitude for seven years.

An officer or servant of the Bank of England or of the Bank of Ireland, who secretes, embezzles, or runs away with any bond, deed, note, bill, dividend warrant, warrant for the payment of any annuity, interest or money, security, money or other effects of or belonging to the Bank of England or Bank of Ireland and entrusted to him or lodged or deposited with the Bank of England or Bank of Ireland, or with him as such officer or servant, is guilty of felony and on conviction thereof liable to penal servitude for life.

The person charged must be one who is acting under and bound to obey the orders of the owner of the property, although his employment need not be permanent. A general deficiency in accounts is not sufficient, but it must be proved that a specific sum of money has been embezzled, just as in larceny proof of the theft of a specific article is necessary. Difficulties sometimes arose where the embezzler had an interest in the property taken, and this was first dealt with by the Larceny Act 1868; now, by s. 40 (4) of the act of 1916, if any person, who is a member of any co-partnership or is one of two or more beneficial owners of any property, embezzles any such property of or belonging to such co-partnership or to such beneficial owners he is liable to be punished as if he had not been or was not a member of such co-partnership or one of such beneficial owners. Again if on the trial of any indictment for embezzlement it is proved that the defendant stole the property in question, the jury may find him guilty of stealing, *i.e.*, larceny.

Under certain circumstances justices may deal summarily with some cases of embezzlement, *e.g.*, by a clerk, a servant or postal official (Criminal Justice Act 1925). *See* also CONVERSION and LARCENY.

Embezzlement, not having existed at the common law, is a crime as provided by the several States in the United States. Embezzlement differs from larceny in that the original taking was lawful or with the consent of the owner, misappropriation following such taking. In some States, the offence is designated as larceny with punishment as such.

EMBLEM, a word applied in Greek and Latin to a raised or inlaid ornament on vases, etc., or to mosaic or tessellated work. In English it is confined to a symbolical representation of some object, particularly to a badge or heraldic device.

EMBLEMENTS, a term applied in English law to the corn and other crops of the earth which are produced annually, not spontaneously but by labour and industry. Emblements belong therefore to the class of *fructus industriales,* or "industrial growing crops" (Sale of Goods Act, 1893, s. 62). They include not only corn and grain of all kinds, but everything of an artificial and annual profit that is produced by labour and manuring; *e.g.*, hemp, flax, hops, potatoes, artificial grasses and clover, but not fruit growing on trees, which come under the general rule *quicquid plantatur solo, solo cedit.* Emblements are included within the definition of goods in s. 62 of the Sale of Goods Act, 1893. Where an estate of uncertain duration terminates unexpectedly by the death of the tenant, or some other event due to no fault of his own, the law gives to the personal representative the profits of crops of this nature as compensation for the tilling, manuring and sowing of the land. If the estate, although of uncertain duration, is determined by the tenant's own acts, the right to emblements does not arise. The right to emblements became of less importance in England after the passing of the Landlord and Tenant Act, 1851. Under s. 1 of that statute as reproduced by s. 14 of the Agriculture Act, 1920, where the lease or tenancy of any farm or lands is held by a tenant at a rack-rent determined by the death or cesser of the estate of any landlord entitled for his life, or any other uncertain interest, the tenant shall continue to hold or occupy such farm or lands until the occupation is determined by a 12 months' notice to quit, expiring at the end of a year of the tenancy, paying a proportionate rent to the successive owner. The right to emblements still exists, however, in favour of (*a*) a tenant not within the Landlord and Tenant Act, 1851, whose estate determines by an event which could not be foreseen, (*b*) the executor, as against the heir of the owner in fee of land in his own occupation, (*c*) an execution creditor under a writ directing seizure of goods and chattels. A person entitled to emblements may enter upon the lands after the determination of the tenancy for the purpose of cutting and carrying away the crops. Emblements are liable to distress by the landlord for arrears of rent, or rent during the period of holding on under the act of 1851 (the Distress for Rent Act, 1737). (*See* DISTRESS.)

The term "emblements" is unknown in *Scots law,* but the heir or representative of a life-rent tenant, a life-renter of lands, has an analogous right to reap the crop (on paying a proportion of the rent) and a right to recompense for labour in tilling the ground. The Landlord and Tenant Act, 1851 (s. 1) was in force in Ireland till 1860, when it was replaced by the Land Act, 1860, which gave to the tenant an almost identical right to emblements (s. 34). (*See* also IRELAND; LANDLORD AND TENANT.)

In the United States the English common law of emblements has been generally preserved.

Under the French Code Civil, the outgoing tenant is entitled to convenient housing for the consumption of his fodder and for the harvests remaining to be got in (art. 1,777). The same rule is in force in Belgium (Code Civil, art. 1,777); and in Holland (Civil Code, art. 1,635); and Spain (art. 1,578). Similar rights are secured to the tenant under the German Civil Code (arts. 592, *et seq.*). French law is in force in Mauritius; the common law of England and the Landlord and Tenant Act, 1851 (14 and 15 Vict., c. 25, s. 1) in many of the British colonies acquired by settlement. In others they are recognized by statute.

EMBOLISM: *see* THROMBOSIS AND EMBOLISM.

EMBOSSING, the art of producing raised portions or patterns on the surface of metal, leather, textile fabrics, cardboard, paper and similar substances. Strictly speaking, the term is applicable only to raised impressions produced by means of engraved dies or plates brought forcibly to bear on the material to be embossed, by various means, according to the nature of the substance acted on. Thus raised patterns produced by carving, chiselling, casting and chasing or hammering are excluded from the range of embossed work. Embossing supplies a convenient and expeditious medium for producing elegant ornamental effects in many distinct industries, and especially in its relations to paper and cardboard its applications are varied and important. Crests, monograms, addresses, etc., are embossed on paper and envelopes from dies set in small handscrew presses, a force or counter-die being prepared in leather faced with a coating of gutta-percha. The dies to be used for plain embossing are generally cut deeper than those intended to be used with colours. Colour embossing is done in two ways—the first and ordinary kind that in which the ink is applied to the raised portion of the design. The colour in this case is spread on the die with a brush and the whole surface is carefully cleaned, leaving only ink in the depressed parts of the engraving. In the second variety—called cameo embossing—the colour is applied to the flat parts of the design by means of a small printing roller, and the letters or design in relief is left uncoloured. In embossing large ornamental designs, engraved plates or electrotypes therefrom are employed, the force or counterpart being composed of mill-board faced with gutta-percha. In working these, powerful screw-presses, in principle like coining or medal-striking presses, are employed. Em-

bossing is also most extensively practised for ornamental purposes in the art of book-binding. The blocked ornaments on cloth covers for books, and the blocking or imitation tooling on the cheaper kinds of leather work, are effected by means of powerful embossing or arming presses. (*See* BOOK-BINDING.) For impressing embossed patterns on wall-papers, textiles of various kinds, and felt, cylinders of copper, engraved with the patterns to be raised, are employed, and these are mounted in calender frames, in which they press against rollers having a yielding surface, or so constructed that depressions in the engraved cylinders fit into corresponding elevations in those against which they press. The operations of embossing and colour printing are also sometimes effected together in a modification of the ordinary cylinder printing machine used in calico-printing, in which it is only necessary to introduce suitably engraved cylinders. For many purposes the embossing rollers must be maintained at a high temperature while in operation; and they are heated either by steam, by gas jets, or by the introduction of red-hot irons within them. The stamped or struck ornaments in sheet metal, used especially in connection with the brass and Britannia-metal trades, are obtained by a process of embossing—hard steel dies with forces or counterparts of soft metal being used in their production. A kind of embossed ornament is formed on the surface of soft wood by first compressing and consequently sinking the parts intended to be embossed, then planing the whole surface level, after which, when the wood is placed in water, the previously depressed portion swells up and rises to its original level. Thus an embossed pattern is produced which may be subsequently sharpened and finished by the ordinary process of carving (*see* WOOD-CARVING; REPOUSSÉ).

EMBOUCHURE: *see* MOUTHPIECE.

EMBRACERY, in law, the attempting to influence a juryman corruptly to give his verdict in favour of one side or the other in a trial, by promise, persuasions, entreaties, money, entertainments and the like. It is an offence, both at common law and by statute, and punishable by fine and imprisonment. As a statutory offence it dates back to 1360. The offence is complete, whether any verdict has been given or not, and whether the verdict is in accordance with the weight of evidence or otherwise. The person making the attempt, and any juryman who consents are equally punishable. The false verdict of a jury, whether occasioned by embracery or otherwise, was formerly considered criminal, and jurors were severely punished, being proceeded against by writ of attaint (*q.v.*). The Juries Act of 1825, in abolishing writs of attaint, made a special exemption as regards jurors guilty of embracery (s. 61).

EMBRASURE, the opening in a battlement between the two solid portions or merlons; a crenel; also the splay or reveal of a window.

EMBROIDERY: *see* TEXTILES.

EMBRUN, a town in the department of the Hautes Alpes in S.E. France. It stands 2,854 ft. above the right bank of the Durance. It is 27½ m. by rail from Briançon and 24 m. from Gap. Pop. (1926) 1,806. Embrun, the *Eburodunum* or *Ebredunum* of the Romans, was the chief town of the province of the Maritime Alps. The episcopal see was founded in the 4th century, and became an archbishopric about 800. In 1147 the archbishops obtained very extensive temporal rights, and the rank of princes of the Holy Roman Empire. In 1232 the county of the Embrunais passed by marriage to the dauphins of Viennois. In 1791 the archiepiscopal see was suppressed, the region being then transferred to the diocese of Gap. The town was sacked in 1585 by the Huguenots and in 1692 by the duke of Savoy. Henri Arnaud (1641–1721), the Waldensian pastor and general, was born at Embrun. Its ramparts were demolished in 1884. Besides the Tour Brune (11th century) and the old archiepiscopal palace, now government offices, barracks, etc., the chief object of interest in Embrun is its cathedral church, 12th century. Above its side door, called the *Réal*, there existed till 1585 (when it was destroyed by the Huguenots) a fresco, probably 13th century, of the Madonna, the object of a celebrated pilgrimage. Louis XI. habitually wore on his hat a leaden image of this Madonna, since between 1440 and 1461, he had been, as dauphin, the ruler of this province.

EMBRYO, the name applied to the developing young of an animal before birth or before hatching from the egg. (*See* EMBRYOLOGY.) The term is also used of that part of a seed (*q.v.*) which will develop into the new plant, in contradistinction to the endosperm of nutritive tissue. (X.)

In the present article a condensed summary is given of the development of the human embryo. Further details and a comparison of the development of man with that of other vertebrates are to be found in the anatomical articles on HEART, NERVOUS SYSTEM, LIVER, etc.

The human embryo, like that of all other vertebrate animals, arises from the union of two minute cells, the *ovum* and *spermatozoon.* This union ("fertilization") takes place in the oviduct, or Fallopian tube of the uterus (*see* REPRODUCTIVE SYSTEM), and results in the formation of a single cell, the *oösperm* or *zygote.* It is by means of these two minute cells, the larger of which is less than 1/100in. across, that hereditary characters are transmitted from parents to offspring. It is generally believed also that the sex of the new individual is determined at the time of fertilization, although it is not possible to distinguish the sex with certainty until the gonads or genital glands are sufficiently advanced in development to recognize the differences in microscopical structure between testis and ovary.

During the child-bearing period from the commencement of menstruation to its cessation about the 45th year, it is believed that a mature ovum is normally discharged from the surface of one of the two ovaries with each menstrual cycle. The ovum is received into the oviduct where it may become fertilized. If this does not take place, it perishes and is discharged.

The process of *ovulation*, or the shedding of a ripe ovum from a ruptured Graafian or ovarian follicle, is associated with menstruation in the following way: The uterus, stimulated by an internal secretion, perhaps derived from cells of the ruptured follicle, prepares for a possible pregnancy, its lining membrane thickens and becomes more vascular, but if fertilization does not take place the thickened lining is unnecessary and breaks down; slight haemorrhage takes place and blood and shreds of membrane are discharged with the degenerated ovum, the whole constituting the menstrual flow. If, however, ovum and spermatozoon have fused, and a zygote becomes imbedded in the mucous lining of the uterus, this discharge does not take place; in other words that cessation of menstruation occurs, which is the first recognizable sign of pregnancy.

Certain of the earlier stages of development have not as yet been completely followed out in the human subject, but those which have been observed confirm the general conclusions, based on the study of other mammalian embryos.

The following description is based partly on observations on segmentation of mammalian embryos other than that of man, but with the exception of these earliest stages the account has been drawn from human material.

During the passage of the fertilized ovum through the oviduct into the cavity of the uterus, it undergoes segmentation or division, and becomes a solid mass of rounded cells, the *morula.* This consists of smaller superficial cells, and larger central cells. The superficial layer, the *trophoblast,* has the important function of absorbing nutriment from the mucous lining of the uterus. The central cells give origin to the embryo. These central cells soon become massed at one pole of the morula, which now assumes an oval form, while at the other pole a cavity appears, so that the solid morula is converted into a hollow vesicle, the *blastula.* The outer wall of this is formed by the trophoblast, which encloses the eccentrically placed *embryonic cell mass,* and a cavity occupied by loose tissue containing fluid in its interstices. The embryonic cell mass is attached by a wide pedicle, the *body stalk* to the inner surface of the epithelial wall of the blastula. Two cavities soon appear within it: the *amniotic cavity,* and the cavity of the *yolk sac.* Between these is a disc shaped zone, where the walls of the two cavities are in contact; this is the embryonic area.

The membrane covering the embryonic area and enclosing the amniotic cavity is the *amnion,* one of the foetal membranes, and

the watery liquid contained within the cavity serves as a protection for the embryo. Later the developing child, now called the foetus, is suspended by the umbilical cord and floats freely in the amniotic fluid. The minute yolk sac of the human embryo is a mere remnant of the large yolk sac found in lower types of vertebrates such as birds and reptiles; in all of the higher mammals its function has been taken over by the *placenta* (*q.v.*). The embryonic area soon becomes oval in form and two axial grooves ("primitive," and "medullary") appear on its upper or dorsal surface. By a growing upward and coalescence of the edges of the anterior or medullary groove, it is converted into a closed tube, the *medullary canal*, which gives rise to the central nervous system and cerebrospinal nerves (*see* BRAIN). This takes place in embryos aged about 25 days and 2·3mm. in length.

Meanwhile the embryonic area becomes encircled by a groove, which by deepening separates the embryo from the amnion and yolk sac. The embryo now assumes a cylindrical form. One end of the hollow tube thus formed is enlarged to form the head and neck; the other, the tail end, becomes curved forward and tapers to a point. On each side of the neck appear four linear furrows, which represent the gill slits of fishes. Bounding these furrows in front and behind are the visceral arches, which correspond to the lower jaw, gill cover and branchial or gill arches of the fishes. At the sixth week the embryo has become nearly circular in outline, and measures about 10 mm. in its greatest diameter. At the head end are developed the mouth, eyes, ears and nasal cavities, and from each side two flattened buds grow outward, which are the rudiments of the upper and lower limbs.

Internally a portion of the yolk sac (archenteron) is separated off from the general cavity and enclosed within the embryo so as to form the alimentary canal. From the forepart of this, glands such as the salivary, thyroid, tonsils and thymus are developed, and as outgrowths from the canal further back, the lungs, liver and pancreas. The main tube gives rise to the pharynx, gullet, stomach and intestine. The heart and blood vessels are formed very early at the 3rd week; and the circulation at first resembles that of a fish, a single tubular heart propelling the blood through a branchial system of vessels.

Afterwards the primary heart and blood vessels are modified so as to form a general circulation for the blood supply of the body and a pulmonary circulation concerned in respiration. The primary branchial system adapted for respiration in water has thus been replaced by a pulmonary system, which enables the child from the time of birth, when the placental circulation is cut off, to breathe air by means of the lungs. During the later months of pregnancy the pulsations of the foetal heart may be heard with a stethoscope, and are a valuable sign of the life of the child.

Deposition of calcium salts to form the bones commences about the 6th week of intra-uterine life, and is accompanied by the formation of the muscles and joints. Development proceeds apace so that movements of the child, spoken of as "quickening," are first felt by the mother about the middle of the fourth month of pregnancy. It must be remembered, however, that although these are a most important sign of life of the child, the new life really commences at the time of fertilization of the ovum.

From the time of the "quickening" until birth, development consists almost entirely of an increase in size, though a recognizable human being has been in existence since about the 6th week of intra-uterine life, when the embryo was less than 12mm. in length. The sex of the future child becomes obvious about the 10th week, though it is possible to distinguish between the external genital organs of the two sexes at a much earlier age, namely about the 6th week. (R. J. G.)

EMBRYOLOGY is the science which treats of the development of an individual animal from its beginning as an egg to a period arbitrarily determined when it has attained or nearly reached its adult structure. With perhaps a very few exceptions all multicellular animals, both Parazoa and Metazoa, reproduce sexually, the new individual arising by a fusion of two cells, one, the spermatozoon, being produced by the male, the other, the ovum or egg, by the female parent. These two reproductive cells always differ greatly in size and appearance but have an equal influence on the characters of the animal arising from their fusion.

The spermatozoon is a small, actively moving cell, which, in the majority of animals, has a very characteristic structure consisting of a head, middle piece and tail. The head is almost entirely occupied by the nucleus, capped by a body called the acrosome and surrounded by a thin layer of cytoplasm. The middle piece is cytoplasmic in nature, containing certain granules, of which the most important are a centrosome which is responsible for the first division of the fertilized egg, and a basal granule which controls the activities of the long tail, a thread of protoplasm, which by its spiral lashing drives the whole forward.

The ovum differs from the spermatozoon in being relatively large and immobile. It is a cell containing a nucleus and much cytoplasm which includes a food store of greater or lesser amount. This food reserve has to supply all the needs of the developing embryo until it becomes capable of feeding. As this event occurs at very different times, the amount of yolk, and hence the size of the egg, varies greatly in different animals.

Fertilization (*q.v.*) is the act of fusion of a spermatozoon with an egg. It is followed immediately by a change of egg-surface which renders it impossible for any more spermatozoa to enter its substance. The entry of a spermatozoon begins a series of activities whose result is the formation from the apparently simple and uniform egg of the elaborately differentiated body of the adult. The first stages of this process are similar in essentials in all Metazoa, but the courses of development of the individuals of the different phyla of the animal kingdom part company at stages depending on the remoteness of their relationship.

After the spermatozoon has entered the egg, usually leaving its tail outside, its head swells up and the fertilized egg contains two very similar nuclei. These approach one another and finally fuse. Meanwhile the centrosome brought in by the sperm has divided into two parts, which separate, a spindle forming between them.

The originally single egg then divides itself into two new cells, the blastomeres of the two-celled stage. These are usually, but not always, exactly similar in appearance. In the case of the sea urchin, *Echinus esculentus*, this division, which is called the first cleavage, takes place about one hour and ten minutes after fertilization and occupies about half an hour.

Subsequently, in *Echinus*, an hour later each of these two blastomeres divides into two, giving rise to a four-celled embryo. The plane of this second cleavage is usually at right angles to that of the first, so that normally the four blastomeres lie in a ring, in contact with one another.

Each of these cells then divides again by a third cleavage, often at right angles to the two which have preceded it. The cleavage of the four cells takes place simultaneously. This process of cleavage is continued until there is built up a mass of some 128 cells, a morula. The morula, if formed at all, typically resolves itself into a blastula in which the cells are arranged in a layer, one cell thick, surrounding a cavity, the segmentation cavity or blastocoel. The blastula is usually larger than the egg from which it has arisen because it has imbibed water from its surroundings.

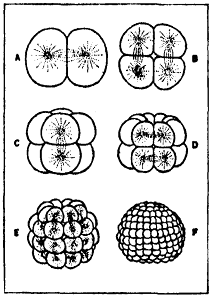
The next process in development is known as gastrulation. It has as its object the formation of a primitive food cavity, the archenteron, surrounded by a double cellular wall, an inner layer of cells, the endoderm or hypoblast, which actually forms the wall of the gut and is concerned with digestion and the absorption of food, and an outer ectoderm or epiblast, which is the part of the embryo which comes into contact with the outside world.

In relatively small eggs this transformation is brought about by the actual intucking of one pole of the blastula into the other. In larger and more yolky eggs so simple a mode of formation is impracticable, and various divergences are found which may be regarded as modifications of the primitive method. Thus, in a frog's egg an actual intucking takes place, but is restricted to one point on the surface of the blastula, and leads to the formation of a shallow pit, subsequently lengthened by a very active localized growth of the part turned in, and a spread of organization from it forward into a mass of cells, which fills most of what should be the blastocoel.

In such eggs as that of a bird the endoderm is formed by the

splitting off of a layer of cells from a comparatively thick mass formed by the cleavage divisions, by a process called delamination.

The gastrula formed by any of these processes corresponds in its fundamental architecture with the adult animals which compose the phylum Coelenterata (*q.v.*). In the development of the members of all higher phyla a third cell layer, the mesoderm, is established. This separates the ectoderm from the endoderm and from it are formed the majority, at any rate, of the muscles of the adult animal, its blood and blood vessels, and the gonads.



FROM E. SELENKA, "DIE KIEMBLATTER DER SCHINODERMEN: STUDIEN ÜBER ENTWICK"

CLEAVAGE OF THE OVUM OF SYNAPTA

A. Two-celled stage, from the side
B. Four-celled stage, from above
C. Eight-celled stage, from the side
D. 16-celled stage, from the side
E. 32-celled stage, from the side
F. 128-celled stage

The mesoderm may arise in many different ways, it may be entirely derived from special blastomeres very early set apart in cleavage, it may come from the endoderm, or from the ectoderm.

In all the higher phyla the mesoderm either is divided into two sheets from its first appearance, or becomes so later; one of these sheets lines the ectoderm and the other encloses the endoderm of the gut. The cavity which separates these mesodermal sheets is the coelom or body cavity. This space, which comes into existence to separate the gut from the body wall, is in most animals connected to the exterior by a canal or canals, the coelomoducts, whose primary function is to extrude the reproductive cells from the coelom in whose wall they have been formed, and into which they have been set free. Subsequently, in the evolution of many forms, these coelomoducts become modified so as to subserve the function of excretion of nitrogenous waste products.

Primitively the coelom with its walls, the primordium of the mesoderm, seems to have arisen as a pouch pushed out from the archenteron, but in the majority of animals this mode of origin has been lost, the mesoderm arising from as few as two cells, early set aside; from mesenchyme cells which have wandered out from the endoderm, or by "delamination" by being cut off as a sheet from the endoderm or even the ectoderm.

Subsequently a split, a schizocoel, appears in the originally solid mesoblast so formed. The embryo at this stage possesses a gut, the enteron, surrounded by the endoderm and communicating with the exterior by a single opening, the blastopore. The ectoderm forms the whole external surface, and from it arise the nervous system and sense organs; in certain embryos arising from eggs which are shed into water, the ectoderm also produces cilia which serve for locomotion and feeding.

At this stage the blastopore often closes completely, only to reopen as the anus, the mouth being formed as a result of the perforation of an area of contact between the endoderm and the ectoderm. When the mouth and anus are established the embryo can begin to feed and passes into the larval stage.

The term larva (*q.v.*) properly implies an animal at a stage in its development when it can feed and move about without having acquired the structure of an adult. The larva may have a very short free life, a few minutes or hours in the case of some molluscs and tunicates, or it may cover the greater part of the individual's existence as in the case of the caterpillars.

The larva may be adapted for a mode of life and even to a medium entirely different from that of the adult animal which it will eventually become; in which case the passage to the adult condition is usually carried out rapidly, by a process involving the destruction of the larval tissues by wandering phagocytic cells and the building up of their material into new adult tissues and organs. Such a transformation is known as a metamorphosis (*q.v.*). It is well illustrated by the mode in which a caterpillar becomes a pupa, all its tissues, except the nervous system and the gonads, becoming reduced to a structureless mass of cells, which are then built up into the body of the butterfly which will emerge from the chrysalis. The larval stage in a life history is thus designed to secure the possibility of growth, under favourable conditions, between the period when the food store originally laid down in the egg is exhausted and that when the adult form is reached.

In animals of very many groups the egg is fertilized within the body of the female which produced it (a process usually requiring special intromittent structures in the male) and may be retained there until development has gone on to some definite point. The new individuals are then expelled either as larvae or as small copies of the parent. This process is called viviparity.

In its early stages this condition implies no more than a retention of the egg inside the mother, but in its fully developed form it involves the provision of food for the growing embryo, either in a condition in which it can be eaten by what is essentially an unborn larva, as in certain fish, or by diffusion into the embryo from the mother's blood, usually through a special organ, the placenta, as in mammals. Viviparity has the advantage that the few young that are born make their appearance at a larger size and far more advanced in structure than would otherwise be possible, and hence have better chances of survival.

It is obvious that a period of development is a necessity for a metazoan: only in such a way can the elaborate body of one of the higher animals be built up from a single cell. It is not, however, clear that such a development must follow so similar a course in all the higher forms. The only explanation is that all these animals are blood relations which owe the differences which separate them to evolution, and that the courses of their development, originally identical, have come to differ by modification of the later stages, cleavage and gastrula remaining much the same in all.

The essentials of this conception were first stated by Carl Ernest von Baer in 1824. Much later Ernest Haekel made a more rigid generalization, his so-called biogenetic law, "that Ontogeny, the development of an individual animal, is a shortened recapitulation of Phylogeny, the evolutionary history of the species to which it belongs." Haekel compared the fertilized egg to a protozoon, the blastula to such a protozoan colony as *Volvox*, the gastrula to a coelenterate and so on. Belief in the general validity of Haekel's law led to an immense activity amongst zoologists in the last quarter of the 19th century. More and more refined methods of observation were elaborated and applied to representatives of all the phyla, and special efforts were made to work out the development of the more primitive members of each group, with the hope, seldom justified by results, that knowledge of it would make plain their phylogenetic relationships. This work, although it can scarcely be said to have succeeded in its original aim, established morphology as a discipline with an accepted technique and theory. It made it certain that development would afford most valuable evidence about the homologies of organs, controlling conclusions reached by comparative anatomy.

The most interesting of the later developments of observational embryology was the study of "cell lineages," which led to the remarkable discovery that the early development of a mollusc followed a most elaborate course, individual cells and small groups of cells being very early set apart for the production of definite structures in the larva and adult. Even more unexpected is the identity of this process in molluscs and annelids.

It must have been realized from the beginning of the study of embryology that there is present in the fertilized egg a mechanism which controls the subsequent development, and the actual course of that development, in such forms as molluscs, suggests that it may be possible to discover its nature.

The only possible method for such an investigation is an experimental one. The course of the development may be modifiable by altering the environment, the temperature, the chemical composition of the water in which it takes place, the space available for the growing embryo, and so on.

On the other hand materials may be removed from the egg or the embryo and any resulting defects noted. Two eggs may be caused to fuse and the history of the joint structure determined. The earliest stage of development, fertilization, may be demon-

strated by such methods to involve two separable processes. One of these, the modification of the egg surface and the beginning of cell division, can, in very many cases, be brought about by chemical means, or even by pricking with a glass needle smeared with blood serum. The other, the change in structure from the bringing in of paternal characters, can clearly not be copied artificially.

The embryo at the two-celled stage may be divided into two, and the subsequent history of the blastomeres traced. In different animals each may develop into a complete but half-sized larva, into a half larva, or one into a complete, the other an incomplete embryo.

Similar experiments may be performed on four- or eight-celled stages, or a blastula may be cut into pieces and their fate determined. The egg may be centrifuged so as to rearrange its constituent parts, subsequently fertilized and allowed to develop, or it may be held upside down so that gravity will disturb the normal orientation of its materials.

From such experiments the conclusion has been reached that the cytoplasm of the egg possesses a structure which determines the course of development, and that it gains this structure before its maturation, whilst the oocyte is growing. Experiments have been designed and carried out with the intention of investigating the period in the development when cells become committed to the formation of certain definite structures or types of structures.

Thus, small pieces of the developing larva of a newt have been transplanted into new regions in corresponding embryos of the same or some other species. They may grow up there, forming part of a complete animal, exactly as if they had been originally formed at that spot. (D. M. S. W.)

EMDEN, a maritime town of Germany, in the Prussian province of Hanover, near the mouth of the Ems. Pop. (1925), 27,777. Emden (Emuden, Emetha) first mentioned in the 12th century, was sold in 1252 to the bishops of Münster, but the episcopal provosts and castellans soon established their practical independence. Towards the end of the 14th century the town gained a considerable trade owing to the permission given by the provost to the pirates known as "Viktualienbrüder" to make it their market, after they had been driven out of Gothland by the Teutonic Order. In 1402, after the defeat of the pirates off Heligoland by the fleet of Hamburg, Emden was besieged, but it was not reduced by Hamburg, with the aid of Edzard Cirksena of Greetsyl, until 1431. The town was held jointly by its captors till 1453, when Hamburg sold its rights to Ulrich Cirksena, who became count of East Friesland. In 1544 the Reformation was introduced, and in the following years numerous Protestant refugees from the Low Countries found their way to the town. In 1595 Emden became a free imperial city under the protection of Holland, and was occupied by a Dutch garrison until 1744 when, with East Friesland, it was transferred to Prussia. In 1810 Emden became the chief town of the French department of Ems Oriental; in 1815 it was assigned to Hanover, and in 1866 was annexed with that kingdom by Prussia. The Ems once flowed beneath its walls, but is now 2 m. distant, and connected with the town by a broad and deep canal, divided into the inner (or dock) harbour and the outer (or "free port") harbour. The latter since the construction of the Ems-Jade and Dortmund-Ems canals, has been deepened to 38 ft., thus allowing the largest sea-going vessels to approach its wharves, while canals bring the town into communication with most of East Friesland, of which it is the commercial capital. Its waterways and its gabled mediaeval houses give it the appearance of an old Dutch, rather than of a German, town. The Reformed "Great Church" (Grosse Kirche) is a large Gothic building completed in 1455 and the Gasthauskirche was formerly the church of a Franciscan friary founded in 1317. The Rathaus (town hall) was built in 1574–76, on the model of that of Antwerp, with a lofty tower, and contains an interesting collection of arms and armour. There are schools of commerce, navigation and telegraphy. Emden trades in agricultural produce and live-stock, horses, timber, coal, tea and wine. The deep-sea fishing industry of the town is important. Machinery, cement, cordage, wire ropes, tobacco, leather, chemicals, etc., are manufactured and shipbuilding is carried on. Emden is also of importance as the station of the submarine cables connecting Germany with England, North America and Spain.

EMERALD, a bright green variety of beryl, valued as a gem-stone. The name comes indirectly from the Gr. σμάραγδος (Arabic *zumurrud*), but seems to have been given to a number of stones having little in common except a green colour.

The properties of emerald are mostly the same as those of beryl. The crystals often show simply the hexagonal prism and basal plane. The prisms cleave, though imperfectly, at right angles to the geometrical axis; and hexagonal slices were formerly worn in the East. Compared with most gems, the emerald is rather soft, its hardness (7·5) being but slightly above that of quartz. The specific gravity is low, varying slightly in stones from different localities, but being for the Muzo emerald about 2·67. The refractive and dispersive powers are not high, so that cut stones show little "fire." The colour is probably due to chromium. F. Wöhler found 0·186% of Cr_2O_3 in the emerald of Muzo—a proportion sufficient to impart an emerald-green colour to glass.

The ancients appear to have obtained the emerald from Upper Egypt, where it is said to have been worked as early as 1650 B.C. It is known that Greek miners were at work in the time of Alexander the Great, and in later times the mines yielded their gems to Cleopatra. Remains of extensive workings were discovered in the northern Etbai by the French traveller, F. Cailliaud, in 1817, and the mines were re-opened for a short time under Mohammed Ali. "Cleopatra's Mines" are situated in Jebel Sikait and Jebel Zabara near the Red sea coast east of Aswan. They were visited in 1891 by E. A. Floyer, and the Sikait workings were explored in 1900 by D. A. MacAlister and others. The Egyptian emeralds occur in mica-schist and talc-schist.

On the Spanish conquest of South America vast quantities of emeralds were taken from the Peruvians, but the exact locality which yielded the stones was never discovered. The only South American emeralds now known occur near Bogotá, the capital of Colombia. The most famous mine is at Muzo, but workings are known also at Coscuez and Somondoco. The emerald occurs in nests of calcite in a black bituminous limestone containing ammonites of Lower Cretaceous age. The mineral is associated with quartz, dolomite, pyrites and the rare mineral parisite (*q.v.*), named after J. J. Paris, who worked the emeralds.

In 1830 emeralds were discovered in the Ural mountains and have been worked on the river Takovaya, about 60m. N.E. of Ekaterinburg, where they occur in mica-schist, associated with aquamarine, alexandrite, phenakite, etc. Emerald is found also in mica-schist in the Habachthal, in the Salzburg Alps, and in granite at Eidsvold in Norway. Emerald has been worked in a vein of pegmatite, piercing slaty rocks, near Emmaville, in New South Wales. The crystals occurred in association with topaz, fluorspar and cassiterite; but they were mostly of rather pale colour. In the United States, emerald has occasionally been found and fine crystals have been obtained from the workings for hiddenite at Stonypoint, Alexander county, N.C.

Many virtues were formerly ascribed to the emerald. When worn, it was held to be a preservative against epilepsy, it cured dysentery, it assisted women in childbirth, it drove away evil spirits, and preserved the chastity of the wearer. It was reputed to have medicinal value, and because of its colour was said to be good for the eyesight.

EMERGENCE. The difference between a mechanical mixture and a chemical compound was among the first things to which the attention of one who entered a laboratory more than half a century ago was directed. He was shown finely pulverized charcoal and sulphur where the relative proportions varied between the limits of 0 and 100% of sulphur. He was then shown the chemical compound labelled CS_2. He was bidden to note the very different effect this produces on the senses. He was taught more about it; the unvarying percentage of sulphur; how light waves behave as

they pass through it; what happens when it is heated; and so on. He learnt in picturesque and imaginative fashion something of its intimate structural organization. He was led to realize that in some way this structure is connected with certain properties and qualities; to realize also that carbon bisulphide comes into being pretty suddenly under certain conditions and not otherwise.

In the Second Series of *Problems of Life and Mind* (1875) George Henry Lewes suggested a new name—not a new concept. That which, under such conditions, springs into being he called "emergent." He held that the nature of an emergent cannot be foretold from the nature of its several constituents as they are in themselves prior to Emergence. Hence the nature of an emergent can be known only through observation and experiment when that emergent has come into being. He contrasted emergents with "resultants." The nature of a mixture of charcoal and sulphur, as resultant, can be foretold from the nature of the assembled particles. In such a resultant there is not a new and unforeseen mode of structural organization; nor is there a new and unforeseen set of properties.

If the word "Emergence" be taken over from Lewes it should be used in the sense he intended. He distinguished between an "empirical" treatment of nature and one that he called "metempirical" (1873) seeking thus to avoid the ambiguities of the word "metaphysical." What he meant by empirical treatment is one which is in accordance with the methods of inductive science. If, on the evidence of observation and experiment, there be Emergence, this is to be taken as it is given *in* nature, leaving others to discuss its alleged introduction *into* nature through some "metempirical" influx. On these terms, which are here accepted, Emergence is a hypothesis of inductive science to be weighed on the available evidence. There can be little doubt that Lewes would have regarded emergent evolution as empirical, and creative evolution as typically "metempirical."

When we apply the distinguishing analysis and synthesis of modern scientific thought to a crystal, that we may piece together its story, it comes, in brief, to this: The proximate constituents are crystal units. The crystal as a whole is, for our unaided vision, the visible and tangible expression of one of a limited number of ways in which these crystal units go together. Under further analysis (distinguishing not destructive) each crystal unit is made up of molecules which go together in a distinctive mode of structural organization; each molecule is made up of atoms which go together in a distinctive way; each atom is made up of electrical charges in proton and electrons; and they too go together in a distinctive manner.

Here we still keep in the neighbourhood of Lewes's starting-point. But we concentrate attention on structural organization, in the crystal unit, in the molecule, and in the atom. Now it may be that the distinctive plan of crystal-organization can be foretold from that of molecular organization, and this from the atomic plan. If this be so the crystal unit is interpretable as the outcome of resultant advance. Or it may be that the crystal unit cannot be foretold from the molecule, nor the molecule from the atom. If that be so each new mode of organization exemplifies Emergence. Of course in either case what actually happens can be generalized after the event under so-called "natural laws."

There seem, then, to be two alternative hypotheses. The alternatives are: (1) *All* events within the crystal are susceptible of resultant treatment (suitably defined); (2) *some* events within the crystal are emergent. In discussing the evidence in support of this hypothesis or that, one must get at the facts of observation and experiment as these facts are interpreted by the scientific expert on the lines of inductive procedure. But we must turn to the logician to say whether it is possible or impossible to foretell the organization of the crystal on the basis of our knowledge of the molecule. To carry the matter yet further, we may ask the experimentalist and the logician to combine forces and tell us whether the whole inorganic world can or cannot be deduced on the basis of our knowledge of, say, the Bohr-Rutherford atom.

The discussion is in progress in the light of present scientific knowledge. It may well be that the advance of knowledge will change the existing position of affairs. But to say that, though not yet, still some day, all events within the crystal, as a sample of the inorganic world, will be shown to be deducibly "resultant," is to anticipate the verdict of the future. We cannot foretell how matters may stand ten years hence. But whatever the verdict of the future may be, the concept of Emergence does here and now raise a crucial question.

But a question wholly different in kind may be raised. It may be asked: How is one *to account for* the sudden or very rapid appearance of new modes of structural organization with which are connected new properties and qualities? The only way in which the man of science professes "to account for" anything that happens is by describing in generalized terms the observed conditions under which it does happen. In this sense those who accept Emergence are bound to render the fullest possible account of these conditions in each instance of its alleged occurrence. It is in this sense that the words "account for" should be used in discussing Emergence as a scientific hypothesis. One does not in science account for the crystal by invoking an extraneous "somewhat" to be discussed in terms of "crystalism."

If we apply distinguishing analysis to the living organism, we come down, when we probe deep enough, to molecules and atoms. But some of the molecules—for example, those of the amino acid constituents of protein—are organized in a special many-linked way. If this distinctive plan of organization can be foreseen on the basis of our knowledge of simpler modes of molecular organization the amino acids, or more comprehensively the biochemical constituents of protoplasm, exemplify resultant advance. But if they cannot be foreseen they exemplify Emergence.

In this field of enquiry the man of science seeks to account for what happens by stating the observable conditions under which it does happen in the living organism or perhaps in the laboratory—not by invoking an extraneous "somewhat" to be discussed by philosophers in terms of "vitalism."

Closely connected with the structural organization and properties of protoplasm there are those processes in the living organism with which it is the task of physiology to deal. Here also for science the question is: Are *all* the events within the living organism susceptible of resultant treatment; or are *some* of these events such as to exemplify Emergence? This is a plain issue.

And when we pass to mental affairs the issue for science is like in kind. On the one hand we have such dim sentience and percipience as may be attributed to the amoeba; on the other hand we have such higher modes of mentality as we attribute to man. Distinguish, say, three stages: percipience, perception, reflective thought. Then ask: Is the mode of organization in reflective thought predictable from that in perception, and that in perception from amoebiform percipience? Or is Emergence exemplified in mental advance no less than in physiological advance and in the advance of events throughout nature? What we need, in the admittedly abstract domain of science, is an evaluation of the evidence in support of Emergence, and its treatment from the standpoint of logic.

EMERITUS, a term used of Roman soldiers and public officials who had earned their discharge from the service, applied, in modern times, to a university professor (*professor emeritus*) who has vacated his chair on account of long service, age, or infirmity, and, in the Presbyterian church, to a minister who has for like reason given up his charge.

EMERSON, RALPH WALDO (1803–1882), American poet and essayist, was born in Boston, Mass., May 25, 1803. Seven of his ancestors were ministers of New England churches. From them Emerson inherited qualities of self-reliance, love of liberty, strenuous virtue, sincerity, sobriety and fearless loyalty to ideals. The form of his ideals was modified by the metamorphic glow of Transcendentalism, but the spirit in which Emerson conceived the laws of life, reverenced them and lived them out, was the Puritan spirit, elevated, enlarged and beautified by the poetic temperament.

His father was the Rev. William Emerson, minister of the First Church (Unitarian) in Boston. Ralph Waldo was the fourth child in a family of eight, of whom at least three gave evidence of extraordinary mental powers. He was brought up in an atmosphere of hard work, of moral discipline, and of wholesome self-sacrifice. His aunt, Mary Moody Emerson, a brilliant and eccentric woman, was a potent factor in his education. In 1817 he entered Harvard college, and graduated in 1821. In scholarship he ranked about the middle of his class. In literature and oratory he was more distinguished, receiving a Boylston prize for declamation and two Bowdoin prizes for ethical dissertations. He was fond of reading and of writing verse, and was chosen as the poet for class day. His cheerful serenity of manner, his tranquil mirthfulness and the steady charm of his personality made him a favourite with his fellows, in spite of a certain reserve.

Immediately after graduation he became for three years an assistant in his brother William's school for young ladies, in Boston. The routine was distasteful; independence, sincerity, reality, grew more and more necessary to him. His aunt urged him to seek retirement, self-reliance, friendship with nature; to be no longer "the nursling of surrounding circumstances." The passion for spiritual leadership stirred within him. In 1825 he entered the divinity school at Cambridge, to prepare himself for the Unitarian pulpit. His studies, much interrupted by ill-health, were, however, far more philosophical and literary than theological.

In Oct. 1826 he was "approbated to preach" by the Middlesex Association of Ministers. The same year a threatened consumption compelled him to take a long journey in the South. Returning in 1827, he continued his studies and preached as a candidate in various churches. In 1829 he married a beautiful but delicate young woman, Ellen Tucker of Concord, and was installed as associate minister of the Second Church (Unitarian) in Boston. The retirement of his senior colleague soon left him the sole pastor. There was a homely elevation in Emerson's early sermons, a natural freshness in his piety, a quiet enthusiasm in his manner, that charmed thoughtful hearers. Early in 1832 he lost his wife, a sorrow that deeply depressed him in health and spirits. Following his passion for independence and sincerity, he arrived at the conviction that the Lord's Supper was not intended by Christ to be a permanent sacrament. He was willing to continue the service only if the use of the elements should be dropped and the rite made simply an act of spiritual remembrance. He found his congregation, not unnaturally, reluctant to agree with him, and therefore retired, not without some disappointment, from the pastoral office. He never again took charge of a parish; but he continued to preach, as opportunity offered, until 1847. In fact, he was always a preacher, his supreme task being to befriend and guide the inner life of man.

The strongest influences in his development about this time were the liberating philosophy of Coleridge, the mystical visions of Swedenborg, the intimate poetry of Wordsworth and the stimulating essays of Carlyle. On Christmas Day 1832 he started on a trip abroad, during which he met Landor, Coleridge, Carlyle and Wordsworth. His visit to Carlyle, in the lonely farmhouse at Craigenputtock, was the memorable beginning of a lifelong friendship. Emerson published Carlyle's first books in America; Carlyle introduced Emerson's essays into England. The two men were bound together by a mutual respect deeper than a sympathy of tastes and a community of spirit stronger than a similarity of opinions. Emerson was a sweet-tempered Carlyle, living in the sunshine. Carlyle was a militant Emerson, moving amid thunderclouds. The things that each most admired in the other were self-reliance, directness, moral courage. A passage in Emerson's diary, written on his homeward voyage, strikes the keynote of his remaining life. "A man contains all that is needful to his government within himself. . . . All real good or evil that can befall him must be from himself. . . . There is a correspondence between the human soul and everything that exists in the world; more properly, everything that is known to man. Instead of studying things without, the principles of them all may be penetrated into within him. . . . The purpose of life seems to be to acquaint man with himself. . . . The highest revelation is that God is in every man." Here is the essence of that intuitional philosophy commonly called Transcendentalism. Nevertheless, Emerson disclaimed allegiance to that philosophy. All through his life he navigated the Transcendental sea, piloted by a clear moral sense, warned off the rocks by the saving grace of humour, and kept from capsizing by a good ballast of New England prudence.

After his return from England in 1833 he went to live with his mother at the old manse in Concord, Mass., and began his career as a lecturer in Boston. His first discourses, delivered before the Society of Natural History and the Mechanics' Institute, were chiefly on scientific subjects, approached in a poetic spirit. In the autumn of 1835 he married Lydia Jackson of Plymouth, having previously purchased a spacious old house and garden at Concord. There he spent the remainder of his life, a devoted husband, a wise and tender father, a careful householder, a virtuous villager, a friendly neighbour, and, spite of all his disclaimers, the central and luminous figure among the Transcendentalists. Some mild departures from established routine he tranquilly tested and as tranquilly abandoned. His theory that manual labour should form part of the scholar's life was checked by the personal discovery that hard labour in the fields meant poor work in the study. "The writer shall not dig," was his practical conclusion. Intellectual independence was what he chiefly desired; and this, he found, could be attained in a manner of living not outwardly different from that of the average college professor or country minister. And yet it was to this property-holding, debt-paying, law-abiding, well-dressed, courteous-mannered citizen of Concord that the ardent and enthusiastic turned as the prophet of the new idealism. The influence of other Transcendental teachers was narrow and parochial compared with that of Emerson. Something in his imperturbable, kindly presence, his commanding style of thought and speech, announced him as the possessor of the great secret which many were seeking—the secret of a freer, deeper, more harmonious life. More and more, as his fame spread, those who "would live in the spirit" came to listen to the voice, and to sit at the feet, of the Sage of Concord.

It was on the lecture platform that he found his power and won his fame. The courses of lectures that he delivered at the Masonic Temple in Boston, during the winters of 1835 and 1836, were well attended and admired. They were followed by two discourses which commanded for him immediate recognition as a new and potent personality. His Phi Beta Kappa oration at Harvard college in August 1837, on "The American Scholar," was an eloquent appeal for independence, sincerity, realism, in the intellectual life of America. His address before the graduating class of the divinity school at Cambridge, in 1838, was an impassioned protest against what he called "the defects of historical Christianity" and a daring plea for absolute self-reliance and a new inspiration of religion. "In the soul," he said, "let redemption be sought. . . . Cast conformity behind you, and acquaint men at first hand with Deity." A blaze of controversy sprang up at once. Emerson made no reply. But amid this somewhat fierce illumination he went forward steadily as a public lecturer. It was not his negations that made him popular; it was the eloquence with which he presented the positive side of his doctrine. Whatever the titles of his discourses, "Literary Ethics," "The Present Age," "The Conduct of Life," their theme was always the same, namely, "the infinitude of the private man." Those who thought him astray on the subject of religion listened to him with delight when he poeticized the commonplaces of art, politics, literature or the household. The simplicity and symmetry of his sentences, the modulations of his thrilling voice, the radiance of his fine face, even his slight hesitations and pauses over his manuscript, lent a strange charm to his speech. For more than a generation he went about the country lecturing, and there was no man on the platform in America who excelled him in distinction, in authority, or in stimulating eloquence.

In 1847 Emerson visited Great Britain for the second time, was welcomed by Carlyle, lectured to appreciative audiences in Manchester, Liverpool, Edinburgh and London, made many new

friends in England and Scotland, paid a brief visit to Paris, and returned home in July 1848. The impressions of this journey were embodied in *English Traits* (1856). The book might be called "English Traits and American Confessions," for nowhere does Emerson's Americanism come out more strongly. But the America that he loved and admired was the ideal, the potential America. For the actual conditions of social and political life in his own time he had a fine scorn. He was an intellectual Brahmin. His principles were democratic, his tastes aristocratic. He loved man, but he was not fond of men. He had grave doubts about universal suffrage. He took a sincere interest in social and political reform, but towards specific "reforms" his attitude was somewhat remote and visionary. He was a believer in woman's rights, but he was lukewarm towards conventions in favour of woman suffrage. For a long time he refused to be identified with the Abolitionists. But as the irrepressible conflict drew to a head, Emerson's hesitation vanished. He said in 1856, "I think we must get rid of slavery, or we must get rid of freedom"; and with the outbreak of the Civil War he became an ardent and powerful advocate of the cause of the Union.

Emerson the essayist was a condensation of Emerson the lecturer. His prose works, with the exception of the slender volume entitled *Nature* (1836), were collected and arranged from the manuscripts of his lectures. His method of writing was characteristic. He planted a subject in his mind, and waited for thoughts and illustrations to come to it, as birds or insects to a plant or flower. When an idea appeared he followed it, "as a boy might hunt a butterfly"; when it was captured he pinned it in his "thought-book." The writings of other men he used more for stimulus than for guidance. "I value them," he said, "to make my top spin." His favourite reading was poetry and mystical philosophy, Shakespeare, Dante, George Herbert, Goethe, Berkeley, Coleridge, Swedenborg, Jakob Boehme, Plato, the new Platonists, and the religious books of the East (in translation). Next to these he valued books of biography and anecdote: Plutarch, Grimm, St. Simon, Varnhagen von Ense. Novels he seldom read. He was a follower of none, an original borrower from all. His illustrations were drawn from near and far. On his pages, close beside the Parthenon, the Sphinx, Etna and Vesuvius, you will find the White mountains, Monadnock, Katahdin, the pickerel weed in bloom, the wild geese honking through the sky, Wall street, cotton mills and Quincy granite. For an abstract thinker, he was strangely in love with the concrete facts of life. From the pages of his teeming notebooks he took the material for his lectures, arranging and rearranging it under such titles as "School," "Genius," "Beauty and Manners," "Self-Possession," "Duty," "The Superlative," "Truth." When the lectures had served their purpose he rearranged the material in essays and published them. Thus appeared in succession the following volumes: *Essays* (1st ser. 1841, 2nd ser. 1844); *Representative Men* (1850); *English Traits* (1856); *The Conduct of Life* (1860); *Society and Solitude* (1870); *Letters and Social Aims* (1876). Besides these, many other lectures were printed in separate form and in various combinations.

Emerson's style is brilliant, epigrammatic, gemlike; clear in sentences, obscure in paragraphs. He was a sporadic observer. He saw by flashes. The coherence of his writing lies in his personality. His work is fused by a steady glow of optimism. Yet he states this optimism moderately. "The genius which preserves and guides the human race indicates itself by a small excess of good, a small balance in brute facts always favourable to the side of reason."

His verse, though in form inferior to his prose, was perhaps a truer expression of his genius. He said, "I am born a poet"; and again, writing to Carlyle, he called himself "half a bard." He had "the vision," but not "the faculty divine" which translates the vision into music. In his two volumes of verse (*Poems*, 1847; *May Day and Other Pieces*, 1867) there are many passages of beautiful insight and profound feeling, some lines of surprising splendour, and a few poems, like "The Rhodora," "The Snow-Storm," "Ode to Beauty," "Terminus," "The Concord Ode," and the marvellous "Threnody" on the death of his first-born boy, of beauty unmarred and penetrating truth. But the total value of his poetical work is discounted by the imperfection of metrical form, the presence of incongruous images, the predominance of the intellectual over the emotional element, and the lack of flow. It is the material of poetry not thoroughly worked out. But the genius from which it came—the swift faculty of perception, the lofty imagination, the idealizing spirit enamoured of reality—was the secret source of all Emerson's greatness as a speaker and as a writer. Whatever verdict time may pass upon the bulk of his poetry, Emerson himself must be recognized as an original and true poet of a high order.

His later years were passed in peaceful honour at Concord. In 1866 Harvard college conferred upon him the degree of LL.D., and in 1867 he was elected an overseer. In 1870 he delivered a course of lectures before the university on "The Natural History of the Intellect." In 1872 his house was burned down, and was rebuilt by popular subscription. In the same year he went on his third foreign journey, going as far as Egypt. About this time began a failure in his powers, especially in his memory. But his character remained serene and unshaken in dignity. Steadily, tranquilly, cheerfully, he finished the voyage of life.

> I trim myself to the storm of time,
> I man the rudder, reef the sail,
> Obey the voice at eve obeyed at prime;
> "Lowly faithful, banish fear,
> Right onward drive unharmed;
> The port, well worth the cruise, is near,
> And every wave is charmed."

Emerson died April 27, 1882, and his body was laid to rest in the peaceful cemetery of Sleepy Hollow, on the edge of Concord.

BIBLIOGRAPHY.—The principal editions of Emerson's *Works* are the Riverside edition prepared by J. E. Cabot (1883–93); the Standard Library edition (1894); and the Centenary edition prepared by Edward Waldo Emerson (1903–04). The *Journals* were edited by E. W. Emerson and Waldo Emerson Forbes (1909–14); and *The Heart of Emerson's Journals*, by Bliss Perry (1926). *The Correspondence of Thomas Carlyle and Ralph Waldo Emerson* (1883) was edited by C. E. Norton, who also edited the *Letters* from Emerson to S. G. Ward (1899); the correspondence between Emerson and Hermann Grimm was edited by F. W. Holls (1903); that between Emerson and John Sterling, by E. W. Emerson (1897); and *Records of a Lifelong Friendship, 1807–1882: Ralph Waldo Emerson and William Henry Furness*, by H. H. Furness (1910). *Uncollected Writings* (1912) includes essays, addresses, poems, reviews and letters.

The principal biographical studies are by A. B. Alcott (1882); Van Wyck Brooks (1927); J. E. Cabot (the authorized biography, 1887); G. W. Cooke (1881); Marie Dugard (1907); O. W. Firkins (1915); Richard Garnett (1888); O. W. Holmes (1885); Alexander Ireland (1882); D. J. Snider (1921); and G. E. Woodberry (1907). Special studies include Joel Benton, *Emerson as a Poet* (1883); Elizabeth L. Cary, *Emerson, Poet and Thinker* (1904); M. D. Conway, *Emerson at Home and Abroad* (1882); E. W. Emerson, *Emerson in Concord* (1889); H. D. Gray, *Emerson* (1917), a study of Emerson's philosophy and of Transcendentalism; J. A. Hill, *Emerson and His Philosophy* (1919); F. B. Sanborn, ed., *The Genius and Character of Emerson: Lectures at the Concord School of Philosophy* (1885); F. W. Wahr, *Emerson and Goethe* (1915); and C. J. Woodbury, *Talks with Ralph Waldo Emerson* (1890). Critical estimates are also to be found in Matthew Arnold's *Discourses in America*, Augustine Birrell's *Obiter Dicta* (2nd ser.), J. J. Chapman's *Emerson and Other Essays*, Henry James's *Partial Portraits*, J. R. Lowell's *My Study Windows*, Maurice Maeterlinck's *On Emerson and Other Essays*, John Morley's *Critical Miscellanies* (vol. i.), Rémy de Gourmont's *Deux Poètes de la Nature*, George Santayana's *Interpretations of Poetry and Religion*, and E. C. Stedman's *Poets of America*. *See* also *A Bibliography of Ralph Waldo Emerson* by G. W. Cooke (1908) and *Ralph Waldo Emerson: How to Know Him* (1921) by S. M. Crothers. (H. VAN D.)

EMERY (Ger. *Smirgel*), an impure variety of corundum, much used as an abrasive or polishing substance, and occurring as a granular or massive, dark-coloured, dense substance, having much the appearance of an iron-ore. Its specific gravity varies with its composition from 3·7 to 4·3. Under the microscope, it is seen to be a mechanical aggregate of corundum, usually in grains or minute crystals of a bluish colour, with magnetite, which also is granular and crystalline. Other iron oxides, like haematite and limonite, may be present as alteration-products of the magnetite. Some of the alumina and iron oxide may occasionally be chemically combined, so as to form an iron spinel,

or hercynite. In addition to these minerals emery sometimes contains diaspore, gibbsite, margarite, chloritoid and sillimanite. Indeed emery must be regarded as a rock rather than a definite mineral species.

The hardness of emery is about 8, whereas that of pure corundum is 9. Its "abrasive power," or "effective hardness," is by no means proportional to the amount of alumina which it contains, but seems rather to depend on its physical condition. Thus, taking the effective hardness of sapphire as 100, J. Lawrence Smith found that the corresponding hardness of the emery of Samos with 70·10% of alumina was 56, that of Naxos, with 68·53 of Al_2O_3, 46, and that of Gumach with 77·82 of Al_2O_3, 47.

Emery has been worked from a very remote period in the Isle of Naxos, one of the Cyclades, whence the stone was called *naxium* by Pliny and other Roman writers. The mineral occurs as loose blocks and as lenticular masses or irregular beds in granular limestone, associated with crystalline schists, and has been found to contain 52·4% of corundum, 32·1 of magnetite, 11·5 of tourmaline, 2 of muscovite and 2 of margarite.

Important deposits of corundum were discovered in Asia Minor by J. Lawrence Smith, when investigating Turkish mineral resources about 1847. The chief sources of emery there are Gumach Dagh, a mountain about 12m. E. of Ephesus; Kula, near Alashehr; and the mines in the hills between Thyra and Cosbonnar, south of Smyrna. The occurrence is similar to that in Naxos. The emery is found as detached blocks in a reddish soil, and as rounded masses embedded in a crystalline limestone associated with mica-schist, gneiss and granite. It is believed to have originated by regional or contact metamorphism of bauxite deposits. The proportion of corundum in this emery is said to vary from 37 to 57%. Emery is worked at several localities in the United States, especially near Chester, Mass., where it is associated with peridotites.

The hardness and toughness of emery render it difficult to work, but it may be extracted from the rock by blasting in holes bored with diamond drills. In the East fire-setting is employed. The emery after being broken up is carefully picked by hand, and then ground or stamped and separated into grades by wire sieves. The higher grades are prepared by washing and elutriation, the finest being known as "flour of emery." A very fine emery dust is collected in the stamping room, where it is deposited after floating in the air, and is used by lapidaries and plate-glass manufacturers. Emery-wheels are made by consolidating the powdered mineral with an agglutinating medium like shellac or silicate of soda or vulcanized india-rubber, and are used not only by dentists and lapidaries but also, on a large scale, in mechanical workshops for grinding, shaping and polishing steel. Emery-sticks, emery-cloth and emery-paper are made by coating the several materials with powdered emery mixed with an adhesive medium. (*See* Corundum.)

EMETICS are substances given for the purpose of producing vomiting. It is customary to divide emetics into central, those which act on the vomiting centre in the medulla, and gastric, those which act directly on the stomach itself. The gastric emetics in common use are alum, ammonium carbonate, zinc sulphate, sodium chloride (common salt), mustard, and warm water. The central emetics are apomorphine, tartar emetic, ipecacuanha, senega, and squill. Of these, tartar emetic and ipecacuanha come under both heads; when taken by the mouth they act as gastric emetics before absorption into the blood, and later produce a further and more vigorous effect by stimulation of the medullary centre. Their action is accompanied by intense depression.

Emetics have two main uses: that of emptying the stomach, especially in cases of poisoning, and that of clearing the air passages, more especially in children. Where possible the first of these is nearly always replaced by use of the stomach pump, whereby depression is avoided. Emetics still have their place, however, in the treatment of bronchitis, laryngitis, and diphtheria in children. Occasionally also they are administered when a foreign body has entered the larynx.

EMIGRANTS' INFORMATION OFFICE: *see* Overseas Settlement Committee.

EMIGRATION, the movement of population out of one country into another. (*See* Migration.)

EMILIA, a territorial division (*compartimento*) of Italy, bounded by Venetia and Lombardy on the N., Liguria on the W., Tuscany on the S., the Marches on the S.E., and the Adriatic Sea on the E. It has an area of 7,967 sq.m., and a population of 2,477,690 (1901), which had grown to 3,033,113 (1921), embracing the provinces of Bologna, Ferrara, Forli, Modena, Parma, Piacenza, Ravenna and Reggio nell' Emilia.

The northern portion is a great plain from the Via Aemilia to the Po; its highest point is not more than 200 ft. above sea-level, while along the east coast are lagoons at the mouth of the Po and those called the Valli di Comacchio to the south of them, and to the south again the plain round Ravenna (10 ft.), which continues as far as Rimini, where the mountains come down to the coast.

Immediately to the south-east of the Via Aemilia the mountains begin to rise, culminating in the central chain of the Ligurian and Tuscan Apennines. The boundary follows the summits of the chain in the provinces of Parma, Reggio and Modena, passing over the Monte Bue (5,915 ft.) and the Monte Cimone (7,103 ft.), while in the provinces of Bologna and Forli it keeps along the N.E. slopes of the chain. With the exception of the Po, the main rivers of Emilia descend from this portion of the Apennines, the majority of them being tributaries of the Po; the Trebbia (which rises in the province of Genoa), Taro, Secchia and Panaro are the most important. Even the Reno, Ronco and Montone, which now flow directly into the Adriatic, were, in Roman times, tributaries of the Po, and the Savio and Rubicon seem to be the only streams of any importance from these slopes of the Tuscan Apennines which ran directly into the sea in Roman times. A considerable amount of electric power is derived from these rivers, and the stations are connected with the Alpine plants, so that interchange at different seasons is possible.

Railway communication in the plain of Emilia is mainly afforded by the line from Piacenza to Rimini. This, as far as Bologna, forms part of the main route from Milan to Florence and Rome, while beyond Rimini it follows the S.E. coast of Italy past Ancona as far as Brindisi and Lecce. The description follows this main line in a south-east direction. Piacenza, being immediately south of a bridge over the Po, is an important centre; a line runs to the west to Voghera, through which it communicates with the lines of west Lombardy and Piedmont, and immediately north of the Po a line goes off to Cremona. A new bridge over the Po carries a direct line from Cremona to Fidenza, and thence to Fornovo, on the line from Parma to Spezia. From Parma starts a main line, which crosses the Apennines to Spezia (and Sarzana, for Pisa and Rome), tunnelling under the pass of La Cisa, while lines run north and north-east to Brescia and Suzzara. From Reggio branch lines run to Guastalla, Carpi and Sassuolo, there being also a line from Sassuolo to Modena. At Modena the line to Verona through Suzzara and Mantua diverges to the north; there is also a branch north-north-east to Mirandola, and another south to Vignola. Bologna is, however, the most important railway centre; besides the line south to Pistoia and Florence over the Apennines (soon to be superseded by a direct line to Prato), and due north to Verona and the line south-east to Rimini, Ancona and Brindisi, there is the main line N.N.E. to Ferrara, Padua and Venice, and there are branches to Budrio and Portomaggiore to the north-east, and to S. Felice sul Panaro and Poggio Rusco to the north which connect the main lines of the district.

At Castel Bolognese, 5 m. N.W. of Faenza, a branch goes off to Lugo, whence there are connections with Budrio, Lavezzola (on the line between Ravenna and Ferrara) and Ravenna, and at Faenza a line goes across the Apennines to Florence. Rimini is connected by a direct line with Ravenna and Ferrara; and Ferrara, besides the main line S.S.W. to Bologna and N. by E. to Padua, has a branch to Poggio Rusco, on the main line between Bologna and Verona. The main products of the plain are cereals, vegetables (tomatoes), wine, and, in the marshy districts near the Po, rice; the system prevailing is that of the mezzadria—half the produce to the owner and half to the cultivator. Beet sugar is produced, the combined production of Emilia and Veneto being 78% of the

total for Italy. Still more, however, might be done with the aid of irrigation and reclamation: the latter is proceeding perhaps more successfully than the former. The ancient Roman divisions of the fields are still preserved in some places. There are also considerable pastures, and cheese is produced, especially Parmesan. Flax, hemp and silkworms are also cultivated, and a considerable quantity of poultry kept. The hill districts produce cereals, vines, olives and fruit; while on the mountains are considerable chestnut and other forests, and extensive summer pastures, the flocks going in part to the Maremma in summer, and in part to the pastures of the plain of the Emilia.

The name Emilia comes from the Via Aemilia (*q.v.*), the Roman road from Ariminum to Placentia, which traversed the entire district from S.E. to N.W., its line being closely followed by the modern railway. The name was transferred to the district (which formed the eighth Augustan region of Italy) as early as the time of Martial, in popular usage, and in the 2nd and 3rd centuries it is frequently named as a district under imperial judges, generally in combination with Flaminia or Liguria and Tuscia. The district of Ravenna was, as a rule, from the 3rd to the 5th century, not treated as part of Aemilia, the chief town of the latter being Placentia. In the 4th century Aemilia and Liguria were joined to form a consular province; after that Aemilia stood alone, Ravenna being sometimes temporarily added to it. The boundaries of the ancient district correspond approximately with those of the modern.

History.—In the Byzantine period Ravenna became the seat of an exarch; and after the Lombards had for two centuries attempted to subdue the Pentapolis (Ravenna, Bologna, Forli, Faenza, Rimini), Pippin took these cities from Aistulf and gave them, with the March of Ancona, to the papacy in 755, to which, under the name of Romagna, they continued to belong. The other chief cities of Emilia—Ferrara, Modena, Reggio, Parma, Piacenza—were independent, and each, whether belonging to Romagna or not, had a history of its own; and, notwithstanding the feuds of Guelphs and Ghibellines, prospered considerably. Pope Nicholas III. obtained control of the Romagna in 1278, but the papal dominion during the Avignon period was only maintained by the efforts of Cardinal Albornoz, a Spaniard sent to Italy by Innocent VI. in 1353. Even so, however, the papal supremacy was little more than a name; and this state of things only ceased when Caesar Borgia, the natural son of Alexander VI., crushed most of the petty princes of Romagna, intending to found there a dynasty of his own; but on the death of Alexander VI. it was his successors in the papacy who profited by what Caesar Borgia had begun. The majority of the towns were thenceforth subject to the church and administered by cardinal legates. In 1796–1814, Emilia was first incorporated in the Italian republic and then in the Napoleonic Italian kingdom; after 1815 Romagna returned to the papacy and its ecclesiastical government, the duchy of Parma was given to Marie Louise, wife of the deposed Napoleon, and Modena to the archduke Francis of Austria, the heir of the last Este. In Romagna and Modena the government was oppressive, arbitrary, corrupt and unprogressive, but in Parma things were better. In 1821 and 1831 there were unsuccessful attempts at revolt in Emilia, which were sternly and cruelly repressed; chronic discontent continued and the people joined again in the movement of 1848–49, which was crushed by Austrian troops. In 1859 the struggle for independence was finally successful, Emilia passing to the Italian kingdom almost without resistance.

EMINENCE, a title of honour now confined to the cardinals of the church of Rome. It was originally given as a complimentary title to emperors, kings, and then to less conspicuous persons. It passed into the Latin of the middle ages as a flattering epithet, and was applied in the church and by the popes to the dignified clergy at large, and sometimes as a form of civility to churchmen of modest rank. On June 10, 1630 Urban VIII. confined the use of the titles *Eminentiae* and *Eminentissimi* to the cardinals, to imperial electors, and to the master of the Hospital of St. John of Jerusalem (order of the Knights of Malta). Since the dissolution of the holy Roman empire, and the entire change, if not actual destruction, of the order of St. John, the title "eminence" has become strictly confined to the cardinals. Before 1630 the members of the sacred college were "illustrissimi" and "reverendissimi."

See du Cange, *Glossarium mediae et infimae latinitatis* (Niort and London, 1884), *s.v.* "Eminentia."

EMINENT DOMAIN, a term applied in law to the sovereign right of a State to appropriate private property to public uses, whether the owner consents or not. It is repeatedly employed by Grotius (*e.g.*, *De jure belli*, bk. iii. c. 20, s. 7), Bynkershoek (*Quaest. jur. pub.*, bk. 2, c. 15), and Puffendorf (*De jure naturae et gentium*, bk. i. c. 1, s. 19)—the two latter, however, preferring the word *imperium* to *dominium;* and by other Dutch jurists. But in modern times it is chiefly in the United States of America that the doctrine of eminent domain has received its application, and it is chiefly to American law that the following remarks refer. Eminent domain is distinguishable alike from the *police power,* by which restrictions are imposed on private property in the public interest, *e.g.*, in connection with the liquor traffic or public health (see *re Haff* [1904], 197 U.S. 488); from the *power of taxation,* by which the owner of private property is compelled to contribute a portion of it for public purposes; and from the *war-power,* involving the destruction of private property in the course of military operations. The police power fetters rights of property; eminent domain takes them away. The power of taxation is analogous to eminent domain as regards the purposes to which the contribution of the taxpayer is to be applied; but, unlike eminent domain, it does not necessarily involve a taking of specific property for those purposes. The destruction of property in military operations, or in the discharge of Government or other duties in cases of necessity, *e.g.*, in order to check the progress of a fire in a city, clearly cannot be said to be an exercise of the power of eminent domain. The question whether the element of compensation is necessarily involved in the idea of eminent domain has in modern times aroused much controversy. According to one school of thought (*see* Lewis, *Eminent Domain,* s. 10), this question must be answered in the negative. According to a second, whose view has the support of the civilians (*see* Randolph, *Eminent Domain,* s. 227; Mills, *Eminent Domain,* s. 1) compensation is an inherent attribute of the power. An intermediate view is advocated by Professor Thayer (*Cases on Constitutional Law,* vol. i. 953), according to which eminent domain springs from the necessities of government, while the obligation to reimburse rests upon the natural right of individuals. The right to compensation is thus not a component part of the power to take, but arises at the same time and the latter cannot exist without it. The relation between the two is that of substance and shadow. The matter is not, however, of great practical importance, for the Federal Constitution prohibits the exercise of the power "without just compensation" (5th Amendment), while in most of the States the State constitution or other legislation has imposed upon it a similar limitation; and the tendency of modern judicial decisions is in favour of the view that the absence of such a limitation will make an enactment so far unconstitutional and invalid.

In order to justify the exercise of the power of eminent domain, the purposes to which the property taken is to be applied must be "public," *i.e.*, primarily public, and not primarily of private interest and merely incidentally beneficial to the public (*Madisonville Traction Co. v. Mining Co.*, 1904, 196 U.S. 239). Subject to this definition, the term "public" receives a wide interpretation. All kinds of property may be taken; and the procedure indicated by the different legislatures must be followed. *See* COMPENSATION. (A. W. R.)

EMINESCU, MICHAIL (1849–1889), the greatest Rumanian poet of the 19th century, was born on Dec. 20, 1849 in Ipateshti near Botoshani, Moldavia. He was of Turco-Tatar origin, and his surname was originally Emin. He studied at Czernowitz, and joined a roving theatrical company where he played in turn the rôles of actor, prompter and stage-manager. After a few years spent in this way, he went to Vienna, Jena and Berlin, where he attended lectures, especially on philosophy. In 1874 he was appointed school inspector and librarian at the university of Jassy, but was soon turned out through the change of govern-

ment, and took charge, as editor-in-chief, of the Conservative paper *Timpul* (Times). In 1883 he had the first attack of the insanity hereditary in his family, and in 1889 he died in Bucharest. In 1870 his great poetical talent was revealed by two contributions to the *Convorbiri literare*, the organ of the Junimist party in Jassy; these were the poems "Venera şi Madona" and "Epigonii." Other poems followed and he was recognized as the first among the modern poets of his country. Mystically inclined and himself of a melancholy disposition, he lived in the glory of the mediaeval Rumanian past; he rebelled against the conventionality of society and his surroundings. Over all his poetry hangs a cloud of sadness, the sense of coming doom. Simplicity of language, masterly handling of rhyme and verse, deep thought and plastic expression made Eminescu the creator of a school of poetry which dominated the thought of Rumania and the expression of Rumanian writers and poets at the end of the 19th century and the beginning of the 20th.

Five editions of his collected poems appeared after 1890. Some of them were translated into German by "Carmen Sylva" and Mite Kremnitz, and others have also been translated into several other languages. Eminescu also wrote two short novels, real poems in prose (Jassy, 1890).

EMIN PASHA (Eduard Schnitzer) (1840–1892), German traveller, was born at Oppeln, Silesia, on March 28, 1840. He graduated M.D. at Berlin, and in 1865 became quarantine medical officer under the Turkish Government at Antivari. From 1870 to 1874 he was in the service of the governor of northern Albania, and adopted a Turkish name. In 1875 he went to Cairo, and next year was invited by Gen. Gordon to join him at Lado on the Upper Nile as medical officer. Gordon sent Schnitzer, now known as Emin Effendi, on missions to Uganda and Unyoro, and in 1878 Emin became governor of the equatorial province of the Sudan, a position which he retained after Gordon's departure. After the abandonment of the Sudan by the Egyptian Government in 1884 Emin Pasha (as he was now styled) was obliged to surrender various posts before the Mahdist advance, and eventually found himself isolated at Wadelai, whither he had removed his capital. There he was relieved by Stanley in April 1888. He does not seem to have welcomed the idea of leaving the province, but eventually he decided to leave with Stanley for the coast.

The German Government now asked him to undertake a new expedition in equatorial Africa with a commission "to secure on behalf of Germany the territories situated south of and along Victoria Nyanza up to Albert Nyanza." But soon after Emin's expedition started the Anglo-German agreement delimitating the British and German spheres of influence and excluding the Albert Nyanza from the German sphere was signed (July 1, 1890), and the political object of Emin's mission was thereby modified. Emin had difficulties with the German authorities in Tanganyika, epidemics among his force and he himself fell ill. In May 1891 he crossed into the Congo Free State; in December he sent the greater part of his caravan, under Dr. Stuhlmann, to the coast, while he himself remained behind with the sick. He encountered the hostility of the Arab traders in slaves and ivory, and was murdered at the instigation of one of these on Oct. 23 or 24, 1892, at Kinena, a place 80m. E.S.E. of Stanley Falls.

See *Emin Pasha in Central Africa* (1888), a collection of Emin's papers contributed to scientific journals; Major G. Casati (1838–1902), an Italian officer who spent several years with Emin, and accompanied him and Stanley to the coast, narrated his experiences in *Dieci anni in Equatoria* (Eng. ed., *Ten Years in Equatoria and the Return with Emin Pasha*, 1891); F. Stuhlmann, *Mit Emin Pascha ins Herz von Afrika* (1894); G. Schweitzer, *Emin Pasha, his Life and Work*, with introduction by R. W. Felkin (1898); A. Kettner, in *Deutsch. Rundschau für Geog.* 26 (1903), 13–17.

EMLYN, THOMAS (1663–1741), English nonconformist divine, was born at Stamford, Lincolnshire. He served as chaplain to the presbyterian Letitia, countess of Donegal, and then to Sir Robert Rich, afterwards (1691) becoming colleague to Joseph Boyse, presbyterian minister in Dublin. From this office he was virtually dismissed on his own confession of unitarianism, and for publishing *An Humble Inquiry into the Scripture Account of Jesus Christ* (1702) was sentenced to a year's imprisonment and a fine of £1,000. Thanks to the intervention of Boyse he was released in 1705 on payment of £90. He is said to have been the first English preacher definitely to describe himself as "unitarian." Emlyn preached a good deal in Paul's Alley, Barbican, in his later years, and died in London in 1741.

EMMANUEL or **IMMANUEL**, a Hebrew symbolical proper name meaning "God (is) with us." At a critical juncture the young King Ahaz of Judah was threatened in 734–733 B.C. by a coalition of north Israel and Syria which aimed at forcing him into an anti-Assyrian alliance. Isaiah, knowing of the King's intention to appeal to Assyria, dramatically intervened to dissuade him, and offered him a sign from Yahweh (Is. vii. 14–16). The actual character and significance of the sign have been variously interpreted (*see* G. B. Gray *ad loc.*). Two main interpretations have emerged: (*a*) any young woman who should within the year bear a son, might call his name Immanuel in token of the divine protection accorded to Judah (a variation of this interprets the mother to be the community of Sion); (*b*) a very attractive view was put forward by Gressmann (*Ursprung*, 1905) who interpreted the passage in the light of ancient eschatological ideas. There was a widespread belief among the people that a wonderful child should be born in the hour of the nation's need who would act as a divine redeemer; the expectation was vague and undefined but well-known, and the prophet makes this idea definite by announcing the advent of the Deliverer. The name, which occurs also in Is. viii. 8, is applied to Christ in Matthew i. 23.

EMMANUEL PHILIBERT (1528–1580), duke of Savoy, son of Charles III. and Beatrice of Portugal, was born on July 8, 1528. Charles, after trying in vain to remain neutral in the wars between France and the emperor Charles V., had been forced to side with the latter, whereupon his duchy was overrun with foreign soldiery and became the battlefield of the rival armies. Prince Emmanuel took service with the emperor in 1545 and distinguished himself in Germany, France and the Low Countries. On the death of his father in 1553 he succeeded to the title. He tried in vain to negotiate a separate peace with France; but in 1556 France and Spain concluded a five years' truce, by which each was to retain what it then occupied. This would have been the end of Savoy, but within a year the two powers were again at war. The chief events of the campaign were the successful resistance of Cuneo, held for the duke by Count Luserna, and the victory of St. Quentin (1557), won by Emmanuel Philibert himself against the French. At last in 1558 the powers agreed to an armistice, and in 1559, under the peace of Cateau-Cambrésis, Emmanuel regained his duchy, but on onerous terms, for France was to occupy several Piedmontese fortresses, including Turin and Pinerolo, for not more than three years, and a marriage was arranged between the duke and Margaret, duchess of Berry, sister of the French king; while Spain was to garrison Asti and Vercelli (afterwards exchanged for Santhià) until France evacuated the above-mentioned fortresses. The duke's marriage took place in Paris a few months later, and he re-entered his dominions. The condition of Piedmont at that time was deplorable, for wars, the exactions and devastations of the foreign soldiery and religious antagonism between Catholics and Protestants had wrought terrible havoc. The duke inaugurated a series of useful reforms, ably assisted by his minister, Niccolò Balbo. But progress was slow, and was accompanied by measures which abolished the states general, the last survival of feudal liberties. Savoy, following the tendency of the other states of Europe at that time, became thenceforth an absolute monarchy.

He had to deal with the vexed question of the Waldenses (*q.v.*) and, though he initiated repressive measures against them, he ended by allowing them a measure of religious liberty in their valleys (1561). He recommenced persecution some years later, but was dissuaded by his duchess and some of the German princes. He next turned his attention to getting rid of the foreign garrisons. In December 1562 the French departed on payment of 100,000 scudi, retaining only Pinerolo and Savigliano, and Turin became the capital once more. There remained the Bernese, who had occupied some of the duke's territories in Savoy and Vaud, and in Geneva, over which he claimed certain rights. With Bern he

made a compromise, regaining Gex, the Chablais, and the Génévois, on condition that Protestantism should be tolerated there, but he renounced Vaud and some other districts (1566). Disagreements with the Valais were settled in a similar way in 1569; but the Genevans refused to recognize Savoyard suzerainty.

Emmanuel reformed the currency, reorganized justice, prepared the way for the emancipation of the serfs, raised the standing army to 25,000 men, and fortified the frontiers, ostensibly against Huguenot raids, but in reality from fear of France. From Henry III., Emmanuel obtained in 1574 the evacuation of Pinerolo and Savigliano. Philip of Spain was likewise induced to evacuate Asti and Santhià in 1575. The duke rounded off his dominions by the purchase of Tenda and Oneglia, which increased his seaboard, and the last years of his life were spent in fruitless negotiations to obtain Monferrato, held by the Gonzagas under Spanish protection, and Saluzzo, which was a French fief. He died on Aug. 30, 1580, and was succeeded by his son Charles Emmanuel I. During the reign of Emmanuel Philibert the duchy, which had been more than half French, became predominantly Italian. He converted it from a ruined and divided land into a respectable independent power of the second rank, and, after Venice, the best-governed state in Italy.

See E. Ricotti, *Storia della monarchia Piemontese,* vol. ii. (Florence, 1861); Claretta, *La Successione di Emanuele Filiberto* (Turin, 1884).

EMMAUS, the name of two, or perhaps three, places in ancient Palestine. (1). Emmaus-Nicopolis (mod. 'Amwās), a town of the maritime plain about 20 m. from Jerusalem, on the road to Ramleh. Here Judas Maccabeus defeated Georgias (166 B.C.) and here, too, Vespasian established a fortified camp (A.D. 69). The name Nicopolis it received from Heliogabalus.

(2). The Emmaus of Luke. St. Luke (xxiv.) makes mention of Emmaus as being 60 stadia (*Codex Sinaiticus* and other mss. have 160) from Jerusalem, but with no indication of direction. Consequently, its location has been sought in all likely places at the shorter or longer radius. Thus Emmaus-Nicopolis (*see* above—176 stadia), Karyet el-'Anab (66), Kuloniyeh (36), El-Kubeibeh (63), 'Urtas (60), and Khirbet el-Khamasa (86), have been separately advocated. Emmaus-Nicopolis has much support. It has the name and a tradition in its favour, but its great distance from Jerusalem makes it difficult, if not impossible, to reconcile it with the details of Luke's narrative. Of the others, El-Kabeibeh and Kuloniyeh have most in their favour. Josephus (*Wars,* vii. 6, 6) speaks of an Emmaus at 30 stadia from Jerusalem, where Vespasian settled 800 veterans, making clear by his manner of reference that he knows of the existence of another Emmaus, presumably that of the Plain. Both the town and its name apparently disappeared, with so many others, in the widespread destruction during the revolt of 132 to 135. The Emmaus of Josephus would seem to accord well with Kuloniyeh (Colonia). Others who rely on mss. reading 60 instead of 30 stadia in Josephus' account, find his Emmaus at El-Kabeibeh, where the ruins of an early church and a tradition in existence in crusading times, place it. El-Kabeibeh, as Emmaus, would satisfy the Josephus account according to some mss., as well as the Lucan according to most mss.

(3). Emmaus (the Hamath of the Old Testament, mod. Hummām) was the name given by the Greeks to the hot springs that lie on the shore of the Sea of Galilee, a mile to the south of Tiberias.

EMMENDINGEN, a town of Germany, in the republic of Baden, close to the Black Forest, on the Elz. Pop. (1925) 8,835. It was formerly the seat of the counts of Hochberg, a cadet branch of the margraves of Baden. In 1418 it received market rights from the emperor, and in 1590 was raised to the status of a town, and walled, by Margrave Jacob III.

Emmendingen has spinning mills, tanneries and manufactories of paper, machinery and cigars. There is also trade in wine.

EMMERICH (the ancient *Embrica*), a town of Germany, in the Prussian Rhine province, on the right bank of the Rhine and the railway from Cologne to Amsterdam, 5m. N.E. of Cleves. Pop. (1925) 13,563. Emmerich, formerly called Embrika and Emrik, originally a Roman colony, is mentioned in records in the 7th century. St. Willibrord founded a monastery and church here. In 1233 the place came into the possession of the dukes of Gelderland and received the status of a town in 1247. In 1371 it fell to the duchy of Cleves, and passed with it in 1609 to Brandenburg. The town joined the Hanseatic League in 1407. It passed into the possession of Prussia in 1815.

It has some shipping trade, and manufactories of tobacco and cigars, chocolate, margarine, oil and sugar. There are also iron foundries and machine factories. The old minster church dates from the middle of the 11th century.

EMMET, ROBERT (1778–1803), Irish rebel, youngest son of Robert Emmet, physician to the lord-lieutenant of Ireland, was born in Dublin in 1778, and entered Trinity college, Dublin, in October 1793 where he had a distinguished academic career, showing special aptitude for mathematics and chemistry and acquiring a reputation as an orator. Without taking a degree he removed his name from the college books in April 1798, as a protest against the inquisitorial examination of the political views of the students conducted by Lord Clare as chancellor of the university. He then turned to political intrigue, being already to some extent in the secrets of the United Irishmen, of whom his elder brother Thomas Addis Emmet (*see* below) was one of the most prominent. In April 1799 a warrant was issued for his arrest, but was not executed; and in 1800 and the following year he travelled on the continent of Europe, where he entered into relations with the leaders of the United Irishmen, exiled since the rebellion of 1798, who were planning a fresh outbreak in Ireland in expectation of support from France. Emmet went to Paris in Oct. 1802, where he had an interview with Bonaparte which convinced him that the peace of Amiens would be of short duration and that a French invasion of England might be looked for in Aug. 1803. The councils of the conspirators were weakened by divided opinions as to the ultimate aim of their policy; and no clearly thought-out scheme of operations appears to have been arrived at when Emmet left Paris for Ireland in Oct. 1802. Those in his confidence afterwards denied that Emmet was himself the originator of the plan on which he acted; and several of the ablest of the United Irishmen held aloof, believing the project to be impracticable. Among the latter was Lord Cloncurry, at one time on the executive of the United Irishmen, with whom Emmet dined the night before he left Paris, and to whom he spoke of his plans with intense enthusiasm and excitement. Emmet's lack of discretion was shown by his revealing his intentions in detail to an Englishman named Lawrence, resident near Honfleur, with whom he sought shelter when travelling on foot on his way to Ireland. Arriving in Dublin at the end of October he received information to the effect that 17 counties were ready to take up arms if a successful effort were made in Dublin. For some time he remained concealed in his father's house near Miltown, making his preparations. A large number of pikes were collected and stored in Dublin during the spring of 1803, but fire-arms and ammunition were not plentiful.

The probability of a French invasion in August was increased by the renewal of the war in May, Emmet's brother Thomas being then in Paris in communication with Talleyrand and Bonaparte. But a discovery by the government of concealed arms, and an explosion at one of Emmet's depots in Patrick Street, necessitated immediate action, and July 23 was accordingly fixed for the projected rising. A plan of operations had been prepared by Emmet, the leading feature of which was a simultaneous attack on the castle, the Pigeon House and the artillery barracks at Island bridge; while bodies of insurgents from the neighbouring counties were to march on the capital. But the whole scheme miscarried. Some of Emmet's proposals, such as a plan for capturing the commander-in-chief, were vetoed by the timidity of his associates. On July 23, all was confusion at the depots, and the leaders were divided as to the course to be pursued; orders were not obeyed; a trusted messenger despatched for arms absconded with the money committed to him to pay for them; treachery, quite unsuspected by Emmet, honeycombed the conspiracy; the Wicklow contingent failed to appear; the Kildare men turned back on hearing that the rising had been postponed; a signal expected by a contingent at the Broadstone was never given. A false report

reached Emmet at one of his depots at nine o'clock in the evening that the military were approaching. Emmet put on a green and white uniform, and placed himself at the head of some 80 men, who marched towards the castle, being joined in the streets by a second body of about equal strength. Lord Kilwarden, proceeding to a hastily summoned meeting of the privy council, was dragged from his carriage by this rabble and murdered, together with his nephew Richard Wolfe; his daughter, who accompanied him, being conveyed to safety by Emmet himself. Emmet, now seeing that the rising had become a mere street brawl, made his escape; a detachment of soldiers quickly dispersed his followers.

After hiding for some days in the Wicklow mountains Emmet repaired to the house of a Mrs. Palmer at Harold's Cross, in order to be near the residence of John Philpot Curran (*q.v.*), to whose daughter Sarah he had for some time been secretly attached. In the hope of persuading this lady to fly with him to America, Emmet lingered in the neighbourhood till Aug. 25, when he was captured. At his trial he was defended and betrayed by the infamous Leonard MacNally (*q.v.*), and was convicted of treason; and after delivering an eloquent speech from the dock, was hanged on Sept. 20, 1803.

Robert Emmet was a youth of modest character, pure motives and winning personality. Thomas Moore, who warmly eulogizes Emmet, with whom he was a student at Trinity college, records that one day when he was playing on the piano the melody "Let Erin remember," Emmet started up exclaiming passionately, "Oh, that I were at the head of 20,000 men marching to that air!" He had no knowledge of the world or of men; he trusted every one with child-like simplicity; except personal courage he had none of the qualities essential to leadership in such an enterprise as armed rebellion. His love affair with Sarah Curran inspired Thomas Moore's well known songs, "She is far from the land where her young hero sleeps," and "Oh, breathe not his name"; it is also the subject of Washington Irving's "The Broken Heart." Emmet was short and slight in figure; his face was marked by smallpox, and he was described in 1803 for the purpose of identification as being "of an ugly, sour countenance and dirty brown complexion." A few poems by Emmet, of little merit, are appended to Madden's biography.

See R. R. Madden, *The United Irishmen, their Lives and Times* (2nd ed. 4 vols., Dublin, 1858–60); Charles Phillips, *Recollections of Curran and Some of his Contemporaries* (2nd ed. 1822); Henry Grattan, *Memoirs of the Life and Times of the Right Hon. H. Grattan* (5 vols. 1839–46); W. H. Maxwell, *History of the Irish Rebellion in 1798; with Memoirs of the Union and Emmet's Insurrection in 1803* (1845); W. H. Curran, *Life of J. P. Curran* (2 vols., Edinburgh, 1822); Thomas Moore, *Life and Death of Lord Edward Fitzgerald* (2 vols. 3rd ed., 1832); and *Memoirs, Journals and Correspondence of Thomas Moore,* edited by Lord John Russell (8 vols., 1853–56).

EMMET, THOMAS ADDIS (1764–1827), Irish lawyer and politician, elder brother of Robert Emmet (*q.v.*), the rebel, was born at Cork on April 24, 1764, and was educated at Trinity college, Dublin, and at Edinburgh University where he studied medicine. After visiting the chief medical schools on the continent, he returned to Ireland in 1788; but the sudden death of his older brother, Christopher Temple Emmet, a barrister of some distinction, induced him to follow the advice of Sir James Mackintosh to forsake medicine for the law as a profession. He was called to the Irish bar in 1790 and quickly obtained a practice, principally as counsel for prisoners charged with political offenses, and he became the legal adviser of the leading United Irishmen. When the Dublin corporation issued a declaration of Protestant ascendancy in 1792, the counter-manifesto of the United Irishmen was drawn up by Emmet; and in 1795 he took the oath of the society in open court, becoming secretary in the same year and a member of the executive in 1797. Emmet was among the more prudent of the United Irishmen on the eve of the rebellion; he engaged in conspiracy with reluctance, and in opposition to bolder spirits like Lord Edward Fitzgerald, he discountenanced the taking up of arms until help should be obtained from France. After the rebellion he was imprisoned with the other leaders at Fort George till 1802. On his release, he went to Brussels, and was involved in the attempt to raise a fresh insurrection with Napoleon's assistance. On the failure of Robert Emmet's rising in 1803, he emigrated to the United States. Joining the New York bar he obtained a lucrative practice and in 1812–13 was attorney-general of New York; his abilities and success being such that Judge Story declared him to be "by universal consent in the first rank of American advocates." He died while conducting a case in court on Nov. 14, 1827. Thomas Emmet married, in 1791, Jane, daughter of the Rev. John Patten, of Clonmel.

See authorities under EMMET, ROBERT; also Alfred Webb, *Compendium of Irish Biography* (Dublin, 1878); C. S. Haynes, *Memoirs of Thomas Addis Emmet* (1829); Theobald Wolfe Tone, *Memoirs,* ed. W. T. W. Tone (2 vols., 1827); W. E. H. Lecky, *Hist. of Ireland in the 18th Century,* vol. iv., 5 vols. (1892).

EMMETT, DANIEL DECATUR (1815–1904), American song-writer, was born at Mount Vernon, Ohio. He started the "negro minstrel" performances, which from 1842 onwards became so popular in America and England, but is remembered particularly as the writer of the famous Southern war-song "Dixie," which he composed in 1859.

EMMITSBURG, a town of Frederick county, Md., U.S.A., 60m. N.W. of Baltimore, near the northern boundary of the State, served by the Emmitsburg railroad. The population was 940 in 1920. Near by are Mount St. Mary's college and Ecclesiastical seminary (Roman Catholic; founded 1808), which has trained many leaders of the Church; and St. Joseph's college for women (incorporated 1816). The town was settled about 1773 and was incorporated in 1824. It was here that the order of the Sisters of Charity was introduced into the United States by Mrs. Elizabeth Ann Seton in 1809.

EMMIUS, UBBO (1547–1625), Dutch historian and geographer, was born at Gretha, East Friesland, on Dec. 5, 1547. After studying at Rostock, he spent two years in Geneva, where he became intimate with Theodore Beza; and returning to the Netherlands was appointed the principal of a college at Norden, a position which he lost in 1587 because, as a Calvinist, he would not subscribe to the Confession of Augsburg. Subsequently he was head of the College at Groningen and when in 1614 this college became a university he was chosen principal and professor of history and Greek at the new university of Groningen and by his wise guidance and his learning speedily raised the new university to a position of eminence. He was on friendly terms with Louis, count of Nassau; corresponded with many of the learned men of his time; and died at Groningen on Dec. 9, 1625. The chief works of Emmius are: *Rerum Frisiarum historiae decades* in six parts, a complete edition of which was published at Leiden in 1616; *Opus chronologicum* (Groningen, 1619); *Vetus Graecia illustrata* (Leiden, 1626); and *Historia temporis nostri* (Groningen, 1732). An account of his life, written by Nicholas Mulerius, was published, with the lives of other professors of Groningen, at Groningen, in 1638.

See his correspondence (2 vols., 1911–22), ed. Brugmans and Wachter.

EMMONS, EBENEZER (1800–1863), American geologist, was born at Middlefield, Mass., May 16, 1800. He studied medicine at Albany, and after taking his degree practised for some years in Berkshire county. His interest in geology was kindled in early life, and in 1824 he had assisted Prof. Chester Dewey (1784–1867) in preparing a geological map of Berkshire county, in which the first attempt was made to classify the rocks of the Taconic area. While undertaking professional work in natural history and geology in Williams college, he also accepted the professorship of chemistry and afterwards of obstetrics in the Albany medical college. The chief work of his life was, however, in geology, and he has been designated by Jules Marcou as "the founder of American palaeozoic stratigraphy, and the first discoverer of the primordial fauna in any country." In 1836 he became attached to the geological survey of the State of New York, and after lengthened study he grouped the local strata (1842) into the Taconic and overlying New York systems. The latter system was subdivided into several groups that were by no means well defined. Emmons had previously described the Potsdam sandstone (1838), and this was placed at the base of the New York system. It is now regarded as Upper Cambrian. In

1844 Emmons for the first time obtained fossils in his Taconic system: a notable discovery because the species obtained were found to differ from all palaeozoic fossils then known, and they were regarded as representing the primordial group. Marcou was thus led to advocate that the term Taconic be generally adopted in place of Cambrian. Nevertheless, the Taconic fauna of Emmons has proved to include only the lower part of Sedgwick's Cambrian. Considerable discussion has taken place on the question of the Taconic system, and whether the term should be adopted; and the general opinion has been adverse. Emmons made contributions on agriculture and geology to a series of volumes on the natural history of New York. He also issued a work entitled *American Geology; containing a statement of the principles of the Science, with full illustrations of the characteristic American Fossils* (1855–57). From 1851 to 1860 he was State geologist of North Carolina. He died at Brunswick, N.C., Oct. 1, 1863.

See the "Biographical Notice of Ebenezer Emmons," by J. Marcou; *Amer. Geologist,* vol. vii. (Jan. 1891), p. 1 with portrait and list of publications.

EMOTION, a vivid feeling and state of excitement induced by the apprehension of some object which arouses an instinctive reaction; *e.g.,* the perception, memory or imagination of any object that threatens danger, and so arouses the instinct of self-preservation, induces an emotion of fear. Similarly with the other emotions. (*See* FEELING, PSYCHOLOGY OF; JAMES-LANGE THEORY OF EMOTIONS; EXPRESSION OF THE EMOTIONS; PSYCHOLOGY.)

EMOTIONS, ANALYSIS OF. The analysis of emotions has two most important aspects. First, attempts are being made to determine the nature of emotion. Second, theoretical and experimental efforts are being undertaken to determine the elementary emotions and to analyze the more complex emotional states into such elements.

There is much dispute among leading authorities as to the nature of emotion. Five principal views are upheld and at present are under experimental investigation.

First, the James-Lange theory, with modifications, is defended by some psychologists (*see* Allport, *Social Psychology*). That theory maintains that all emotions consist ultimately of sensations. James emphasized sensations resulting from skeletal movements caused by the exciting object, and sensations caused directly by the exciting object itself. Lange emphasized visceral sensations, caused by movements of the viscera resulting from perception of the exciting object. Some writers follow James' emphasis, some follow Lange's, and some give approximately equal weight to both types of sensation as components of emotion.

Three lines of experimental evidence weigh against acceptance of any version of the James-Lange theory. First, Lenander, Sherrington, Goltz, Cannon and others have produced much physiological evidence against the theory. Visceral sensations have been shown to be very sparse, with a small number of receptor organs for sensation located in the viscera. Dogs have been shown to retain their former emotions unimpaired and even to experience emotions never felt before, when nearly all visceral change has been prevented by appropriate spinal transection. On the other hand, when a sufficient portion of the central nervous system (brain) has been removed, only the emotion of rage persists. Another line of evidence, advanced by Cannon and others, shows that visceral changes must be virtually identical during many different emotions. Second, experimenters (Marañon) have shown that administration of adrenalin, which produces the very visceral sensations said to compose emotion, does not in fact cause emotion in human subjects, unless the appropriate emotional *idea* is also supplied by suggestion or previous experience. Third, psychological experiments (Blatz, Marston, Brunswick) indicate that the emotion occurs more quickly than the visceral changes, does not run parallel with the visceral changes, and can be distinguished introspectively from sensations which may or may not accompany it (Nafe, Conklin and Dimmick, Titchener, Cornell Laboratory). The James-Lange theory, though still under experimental investigation, seems quite definitely disproved.

Second, some behaviourists hold a view closely akin to Lange's theory but much more radical in that the bodily changes themselves, and not their sensations, are regarded as constituting the emotion. These behaviourists, of course, deny the existence of consciousness of any sort, their emotion theory being but a corollary of this general position. (For evidence on this issue *see* the article on CONSCIOUSNESS.) The behaviourists distinguish between emotional and other responses simply by defining all visceral changes as emotional. Therefore, the same evidence cited against the James-Lange theory likewise weighs against their contention.

Third, those psychologists who still uphold the concept of instinct regard emotion as one aspect of the consciousness accompanying instinctive behaviour patterns. This view has been carried still further by regarding emotion as the "inner" or "subjective" or "self" aspect of all action. Another slightly different version holds that emotion occurs only when the basic instincts or "drives" are blocked by some obstacle in the environment, or are thwarted by malfunctioning of the individual organism. The number of instincts, with corresponding emotions, varies considerably in different theories. McDougall gives 13 major and 7 minor instincts; Colvin 30; Kirkpatrick 30; James originally described 52; and Woodworth seems to accept about 110. These large and varying numbers of ultimately different emotions accepted by the instinctivists appear to offer little hope of finding any common factor upon which all would agree as the true nature of emotion. Experimental proof of this view of emotion depends upon proof or disproof of instinct. Experiments in animal psychology are best adapted to this problem.

Fourth, the tenets of leading psycho-analysts assume a libido, with either one or two fundamental departments, sex, or sex and ego. This view is really very close to that of the instinctivists, as McDougall points out (*Body and Mind*); since both sex and ego can be thought of as little else than basic instincts with corresponding and accompanying emotions. The physiological basis of the libido and its emotions is hazy, to say the least. Experimental testing of this view of the ultimate nature of emotion is therefore impossible. But social and group-analysis studies (Trigant Burrow) are seeking to amass evidence that the libido's dynamic drives and emotions underlie all human conduct.

Fifth, there are psychological and physiological theories which regard emotion and feeling as distinctive consciousness products of certain portions of the brain or nervous system (Cannon). A recent (1927) integrative theory of this type maintains that affection is motor consciousness generated by integration of nervous impulses in the motor centres, just as sensation is sensory consciousness generated by integration of impulses in the sensory centres (Marston). According to this view some affective awareness must accompany all bodily action brought about by activity of the central nervous system. In this respect the theory agrees with the essential point of both the instinctive and psychoanalytical views, and with James's original assertion that awareness of bodily changes as they occur is the emotion. Some experimental verification of this theory has been found, but adequate technique for a crucial test of the theory has not yet been perfected. It is, however, clearly subject to experimental proof or disproof.

The second important aspect of analysis of emotions concerns various attempts to discover primary or elementary emotions, from which all other emotions are built up. One view of this problem, maintained by some behaviouristic experimenters, holds that there is no such thing as a discreet, individual emotion, qualitatively distinct from all others, but that "general emotionality" (Landis) only exists. This theory is based upon a failure to find distinctive emotional expressions in the form of invariable bodily changes for any of the emotions (fear, rage, etc.) experimentally evoked, and thus presumes, without investigation, that fear, rage, etc., are ultimately simple emotion elements, and also that simple emotion elements must produce uniform bodily changes.

Other theories which postulate more or less specific primary emotions, or emotion elements, are those of the instinctivists and

psychoanalysts, already discussed. The selection by the psychoanalysts of love (sex) and appetite (ego-emotion) as emotion elements is based upon a great deal of clinical data; but the concepts of sex and ego thus arrived at clearly depict compound and not simple emotion elements.

Recent psychological findings suggest a definite neurological basis for love and appetite as the two basic compound emotions, and further present evidence for the existence of two simpler emotion elements in each compound (Marston). Appetite is composed of compliance and dominance, and love is composed of inducement and submission. Fear results from over-compliance, rage from over-dominance, and other destructive emotions from conflicts and maladjustments between the four emotion elements.

Watson's findings with regard to emotion elements in young infants closely accord with those just given. Watson finds only three emotions in children, but one of those three, love, includes descriptions of both inducement and submission emotions. Watson terms all compliance emotion fear, and all dominance rage. The classifications of emotion elements by Watson and Marston are in close agreement.

The only basis for emotional analysis of human beings in need of personality readjustment has been introspective reports, with reports of dreams and free associations therefrom. These have furnished an extremely indefinite and subjective basis for psychoanalytical procedures, which have nevertheless accomplished surprisingly effective practical results. When emotion elements are identified objectively, by observing the subject's behaviour, personality analysis and readjustment is placed upon a scientific basis, with promise of greater success.

Marston, "Motor Consciousness as a Basis for Emotion," *J. Abn. & Soc. Psych.* (Sept., 1927); J. B. Watson, *Behaviourism.* (W. M. M.)

EMPATHY, a term used as the equivalent of the German *Einfühlung,* which is very difficult to translate. It is modelled on the word sympathy. The term is used with special (but not exclusive) reference to aesthetic experience. The most obvious example perhaps is that of the actor or singer when he *feels* the part he is performing or (better perhaps) reading or studying. Similarly with other works of art. One may, by a kind of introjection, "feel oneself into" what one observes or contemplates. Whereas in empathy proper the observer assimilates himself to his aesthetic object, in animism he assimilates an inanimate object to himself. This latter process is much easier than the former; and no doubt it happens often enough in aesthetic experience that the subject assimilates the aesthetic object to himself, though he may mean to assimilate himself for the time being to his object, to be sympathetic with it. *See* AESTHETICS.

See also T. Lipps, *Aesthetik* (1903); J. Volkelt, *System der Aesthetik* (1905, etc.); D. W. H. Parker, *The Analysis of Art* (1927).

EMPEDOCLES (*c.* 490–430 B.C.), Greek philosopher and statesman, a citizen of Akragas in Sicily. It seems that he carried on the democratic tradition of his distinguished family by helping to overthrow an oligarchic government which succeeded the tyranny in Agrigentum, but refused the invitation of the citizens to become their king. Later he left the city, and died in the Peloponnese in 430.

Of his poem on nature (φύσις) there are left about 400 lines in unequal fragments out of the original 5,000; of the hymns of purification (καθαρμοί) less than 100 verses remain; of the other works, improbably assigned to him, nothing is known. His grand but obscure hexameters, after the example of Parmenides, delighted Lucretius. Aristotle, it is said, called him the father of rhetoric, and Galen regarded him as the founder of the Italian medical school. To his contemporaries he seemed more than a mere man, and the people of Agrigentum have never ceased to honour his name; even in modern times he has been celebrated by followers of Mazzini as the democrat of antiquity *par excellence.*

As his history is uncertain, so are his doctrines. He is at once a believer in Orphic mysteries, and a scientific thinker. There are, he holds, four ultimate unchangeable elements, four primal divinities, of which are made all structures in the world—fire, air, water, earth. These four roots of all things are eternally brought into union, and eternally parted by two active corporeal forces, love and strife—forces which can be seen working amongst men, but which really pervade the whole world. Nothing new comes or can come into being; the only change that can occur is a change in the juxtaposition of element with element.

Empedocles seems to have conceived a period when love was predominant, and all the elements formed one great sphere. Since that period discord gained more sway; the actual world was full of contrasts and oppositions, due to the combined action of both principles. His theory attempted to explain the separation of elements by strife, the formation of earth and sea, of sun and moon, of atmosphere. His most interesting views dealt with the origin of plants and animals, and with the physiology of man. As the elements combined through the work of love, there appeared quaint results—heads without necks, arms without shoulders. Then as these structures met, there were seen horned heads on human bodies, bodies of oxen with men's heads, and figures of double sex. But most of these disappeared as suddenly as they arose; only in those rare cases where the several parts were adapted to each other did the complex structures last. Soon various influences reduced the creatures of double sex to a male and a female, and the world was replenished with organic life. This theory seems a crude anticipation of the modern "survival of the fittest" theory.

As man, animal and plant are composed of the same elements in different proportion they have an identity of nature. They all have sense and understanding, mind in man being always dependent upon the body. Hence the precepts of morality are with Empedocles largely dietetic. Knowledge is explained by the principle that the several elements in things are perceived by the corresponding elements in ourselves. Like is known by like. The organs of sense are specially adapted to receive the effluxes from bodies around us; and in this way arises perception which is not merely passive. The heart, not the brain, is the organ of consciousness. According to Aristotle, Empedocles made no distinction between perception and thought.

It is not easy to harmonize these theories with the Pythagorean theory of transmigration of souls which Empedocles seems to expound. Probably the doctrine that the divinity (δαίμων) passes from element to element, nowhere finding a home, is a mystical way of teaching the continued identity of the principles which are at the bottom of every phase of development from inorganic nature to man. At the top of the scale are the prophet and the physician, those who have best learned the secret of life; they are next to the divine. It is the business of the philosopher to lay bare the fundamental difference of elements, and to display the identity between what seem unconnected parts of the universe.

EMPEROR, a title formerly borne by the sovereigns of the Roman empire (*see* EMPIRE), and since their time, partly by derivation, partly by imitation, used by a variety of other sovereigns. Under the republic, the term *imperator* applied in theory to any magistrate vested with *imperium;* but in practice it was only used of a magistrate who was acting abroad (*militiae*) and was thus in command of troops. The term *imperator* was the natural and regular designation employed by his troops in addressing such a magistrate; but it was specially employed by them to salute him after a victory; and when he had been thus saluted he could use the title of *imperator* in public till the day of his triumph

at Rome, after which it would lapse along with his *imperium*. The senate itself might, in the later republic, invite a victorious general to assume the title; and in these two customs—the salutation of the troops and the invitation of the senate—we see in the germ the two methods by which under the empire the *princeps* was designated; while in the military connotation attaching to the name even under the republic we can detect in advance the military character by which the emperor and the empire were afterwards distinguished. Julius Caesar was the first who used the title continuously (from 58 B.C. to his death in 44 B.C.), as well *domi* as *militiae;* and his nephew Augustus took a further step when he made the term *imperator* a *praenomen*, a practice which after the time of Nero becomes regular. But apart from this amalgamation of the term with his regular name, and the private right to its use which that bestowed, every emperor had an additional and double right to the title on public grounds, possessed as he was of an *imperium infinitum maius*, and commanding all the troops of the empire. The title *imperator* was conferred by the senate; and an emperor normally dates his reign from the day of his salutation by the senate. But the troops were also regarded as still retaining the right of saluting an *imperator;* and there were emperors who regarded themselves as created by such salutation and dated their rights accordingly. The military associations of the term thus resulted, only too often, in making the emperor the nominee of a turbulent soldiery.

Augustus had been designated (not indeed officially, but none the less regularly) as *princeps*—the first citizen of the State. The designation suited the early years of the empire, in which a dyarchy of *princeps* and senate had been maintained. But by the 2nd century the dyarchy is passing into a monarchy: the title of *princeps* recedes, and the title of *imperator* comes into prominence to designate not merely the possessor of a certain *imperium*, or the general of troops, but the simple monarch in the fullness of his power as head of the State. From the days of Diocletian there are occasionally two emperors, but not, at any rate in theory, two empires; the two emperors are the dual sovereigns of a single realm. But from the time of Arcadius and Honorius (A.D. 395) there are in reality (though not in theory) two empires as well as two emperors, one of the East and one of the West.

On the revival of the Roman empire in the West by Charlemagne in 800, the title (at first in the form *imperator*, or *imperator augustus*, afterwards *Romanorum imperator augustus*) was taken by him and by his Frankish, Italian and German successors, heads of the Holy Roman empire, down to the abdication of the Emperor Francis II. in 1806. The doctrine had, however, grown up in the earlier middle ages (about the time of the Emperor Henry II., 1002–24) that although the emperor was chosen in Germany (at first by the nation, afterwards by a small body of electors), and entitled from the moment of his election to be crowned in Rome by the pope, he could not use the title of emperor until that coronation had actually taken place. The German sovereign, therefore, though he exercised, as soon as chosen, full imperial powers both in Germany and Italy, called himself merely "king of the Romans" (*Romanorum rex semper augustus*) until he had received the sacred crown in the sacred city.

In mediaeval times the emperor, conceived as vicegerent of God and co-regent with the pope in government of the Christian people committed to his charge, might almost be regarded as an ecclesiastical officer. Not only was his function regarded as consisting in the defence and extension of true religion; he was himself arrayed in ecclesiastical vestments at his coronation; he was ordained a subdeacon; and, assisting the pope in the celebration of the Eucharist, he communicated in both kinds as a clerk. The same sort of ecclesiastical character came also to be attached to the tsars[1] of Russia, who—especially in their relations with the Orthodox Eastern Church—might have vindicated for themselves (though the sultans of Turkey have disputed the claim) the succession to the East Roman emperors (*see* EMPIRE). But the title of emperor was also used in the middle ages, and is still used, in a loose and vague sense, without any ecclesiastical connotation or hint of connection with Rome (the two attributes which should properly distinguish an emperor), and merely in order to designate a non-European ruler with a large extent of territory. It was thus applied to the rulers of China and Japan; it was attributed to the Mogul sovereigns of India; and since 1876 it has been used by British monarchs in their capacity of sovereigns of India (*Kaiser-i-Hind*).[1]

Since the French Revolution and during the course of the 19th century the term emperor has had an eventful history. In 1804 Napoleon took the title of "Emperor of the French," and posed as the reviver of the empire of Charlemagne. Afraid that Napoleon would next proceed to deprive him of his title of Holy Roman emperor, Francis II., in 1804, invested himself with a new title, that of "Hereditary Emperor of Austria," and then, in 1806, abdicated his old, historical title and dissolved the Holy Roman empire. Thus the old and true sense of the term emperor —the sense in which it was connected with the Church in the present and with Rome in the past—finally perished; and the term became partly an apanage of Bonapartism (Louis Napoleon resuscitated it as Napoleon III. in 1853), and partly a personal title of the Hapsburgs as rulers of their various family territories. In 1870, however, a new use of the title was begun, when the union of Germany was achieved, and the Prussian king, who became the head of united Germany, received in that capacity the title of German emperor. Here the title of emperor designated the president of a federal State; and here the Holy Roman emperor of the 17th and 18th centuries, the president of a loose confederation of German States, may be said to have found his successor. But the term has been widely and loosely used in the course of the 19th century. It was the style from 1821 to 1889 of the princes of the house of Braganza who ruled in Brazil; it has been assumed by usurpers in Haiti, and in Mexico it was borne by Augustin Iturbide in 1822 and 1823, and by the ill-fated Archduke Maximilian of Austria from 1864 to 1867.

See J. Selden, *Titles of Honour* (1672); Sir E. Colebrooke, "On Imperial and Other Titles" in the *Journal of the Royal Asiatic Society* (1877); J. Bryce, *Holy Roman Empire* (1904). *See* also the articles on "Imperator" and "Princeps" in Smith's *Dictionary of Greek and Roman Antiquities.*

EMPEROR-FISH (*Holocanthus imperator*), a large and gorgeously coloured coral fish of the family *Chaetondontidae* (butterfly fishes, *q.v.*), reaching a length of 15 in. and found from East Africa to Malaya. It is an excellent table-fish.

EMPETRACEAE, a family of dicotyledonous plants the best known member of which is the crowberry (*q.v.*) There are only four species, in three genera, confined to the northern hemisphere and the Andes. The parts of the flowers are in threes and the fruit is a drupe.

EMPHYSEMA, a medical term applied to two conditions—"pulmonary emphysema" (the word "pulmonary" is frequently omitted) and "surgical emphysema." Of pulmonary emphysema there are two forms, vesicular and interstitial (or interlobular). In vesicular emphysema there is enlargement of air-vesicles, from excessive distension and destruction of the septa between contiguous vesicles (*see* RESPIRATORY SYSTEM). In interstitial emphysema air is present in the connective tissue beneath the pleura and between the pulmonary air-cells.

The former variety is by far the more common and generally is caused by forced expiration against a closed glottis, as in coughing. Hence emphysema is most evident over relatively

[1]The word *Tsar*, like the German *Kaiser*, is derived from Caesar (*see* TSAR). Peter the Great introduced the use of the style "Imperator," and the official designation afterwards became "Emperor of all the Russias, Tsar of Poland, and Grand Duke of Finland," though the term tsar was still popularly used in Russia.

[1]For the titles of βασιλεύς, *Imperator Augustus*, etc., applied in the 10th century to the Anglo-Saxon kings, *see* EMPIRE (note). The claim to the style of emperor, as a badge of equal rank, played a considerable part in the diplomatic relations between the sultan and certain European sovereigns. Thus, at a time when this style (padishah) was refused by the sultan to the tsars of Russia, and even to the Holy Roman emperor himself, it was allowed to the French kings, who in diplomatic correspondence and treaties with Turkey called themselves "emperor of France" (*empereur de France*).—(ED.)

unsupported parts of the lungs, *e.g.*, above the collar bone and between the ribs. Probably an impaired nutritive condition of the lung tissue conduces towards the change. Emphysema is a progressive condition, since the distended air vesicles have lost their elasticity. Moreover, many of the pulmonary capillary blood vessels which run in the inter-vesicular septa have been destroyed and the rest are elongated and narrowed. Hence an increased strain is thrown on the right ventricle, with a consequent dilatation leading on to heart failure and all its attendant troubles. The chief symptom in this complaint is shortness of breath, more or less constant, but greatly aggravated by exertion and by attacks of bronchitis, to which persons suffering from emphysema appear to be specially liable. The respiratory rhythm is altered, the expiratory portion being far longer than the inspiratory. In severe forms of the disease the patient has a puffy cyanosed appearance and the chest becomes barrel-shaped.

Interstitial emphysema, arising from the rupture of air-cells in the immediate neighbourhood of the pleura, may occur as a complication of the vesicular form, or separately as the result of some sudden expulsive effort, such as a fit of coughing, or, as has frequently happened, in parturition. Gangrene or post-mortem decomposition may lead to the presence of air in the interstitial tissue of the lung. Occasionally the air infiltrates the cellular tissue of the posterior mediastinum, and distends the whole surface of the body.

Surgical emphysema signifies the effusion of air into the general connective tissues of the body. The commonest causes are a wound of some air-passage, or a penetrating wound of the chest wall without injury to the lung. Its severity varies, from a little crepitation felt under the skin to extreme cases where the whole body is blown up and death is imminent from impeded respiration and failure of the action of the heart. In mild cases no treatment is necessary, as the air gradually becomes absorbed; but in severe cases incisions must be made in the swollen cellular tissues to allow the air to escape. The condition must be distinguished from those in which gas is formed in the tissues during the growth of pathogenic bacteria (*e.g.*, gas gangrene).

EMPIRE, a term used to denote a state of large size and also (as a rule) of composite character, often, but not necessarily, ruled by an emperor—a state which may be a federation, like the German empire from 1870 to 1918, or a unitary state, like the Russian empire before its collapse, or even, like the British empire, a loose commonwealth of free states united to a number of subordinate dependencies. For many centuries the writers of the church, basing themselves on the Apocalyptic writings, conceived of a cycle of four empires, generally explained—though there was no absolute unanimity with regard to the members of the cycle—as the Assyrian, the Persian, the Macedonian and the Roman. But in reality the conception of empire, like the term itself (Lat. *imperium*), is of Roman origin. The empire of Alexander had indeed in many ways anticipated the empire of Rome. "In his later years," Bury writes, "Alexander formed the notion of an empire, both European and Asiatic, in which the Asiatics should not be dominated by the European invaders, but Europeans and Asiatics alike should be ruled on an equality by a monarch, indifferent to the distinction of Greek and barbarian, and looked upon as their own king by Persians as well as by Macedonians." The contemporary Cynic philosophy of cosmopolitanism harmonized with this notion, just as Stoicism did later with the practice of the Roman empire: Alexander, like Diocletian and Constantine afterwards, accustomed a Western people to the forms of an Oriental court; and he anticipated the Roman Caesars in claiming and receiving the recognition of his own divinity. But when he died in 323, his empire, which had barely lasted ten years, died with him; and it was divided among Diadochi who, if in some other respects (as, for instance, the Hellenization of the East) they were heirs of their master's policy, were destitute of any general conception of empire. The work of Alexander was rather that of the forerunner than the founder. He prepared the way for the world-empire of Rome; he made possible the rise of a universal religion. And these are the two factors which, throughout the middle ages, went together to make the thing which men called empire.

The Roman Empire.—At Rome the term *imperium* signified generally, in its earlier use, the sovereignty of the state over the individual, a sovereignty which the Romans had disengaged with singular clearness from all other kinds of authority. Each of the higher magistrates at Rome was vested, by a *lex curiata,* passed by the people (for power was distinctly conceived as resident in, and delegated by, the community), with an *imperium* both civil and military, which varied in degree with the magnitude of his office. In the later days of the republic such *imperium* was enjoyed, partly in Rome by the resident consuls and praetors, partly in the provinces by the various proconsuls or propraetors. There was thus a certain *morcellement* of *imperium,* delegated as it was by the people to a number of magistrates: and the coming of the empire meant the reintegration of this *imperium,* and its unification, by a gradual process, in the hands of the *princeps,* or emperor. The means by which this process was achieved had already been anticipated under the republic. Already in the days of Pompey it had been found convenient to grant to an extraordinary officer an *imperium aequum* or *majus* over a large area, and that officer thus received powers, within that area, equal to, or greater than, the *imperium* of the resident governors. This precedent was followed by Augustus in the year 27 B.C., when he acquired for himself sole *imperium* in a certain number of provinces (the imperial provinces), and an *infinitum imperium maius* in the remaining provinces (which were termed senatorial). As a result, Augustus enjoyed an *imperium* coextensive indeed with the whole of the Roman world, but concurrent, in part of that world, with the *imperium* of the senatorial proconsuls; and the early empire may thus be described as a dyarchy. But the distinction between imperial and senatorial provinces finally disappeared: by the time of Constantine the emperor enjoyed sole *imperium;* and an absolute monarchy had been established. We shall not, however, fully understand the significance of the Roman empire unless we take also into account the importance of its military aspect. All the soldiers of Rome had from the first to swear *in verba Caesaris Augusti;* and thus the whole of the Roman army was his army, regiments of which he might indeed lend, but of which he was sole *Imperator* (*see* under EMPEROR). Thus regarded as a permanent commander-in-chief, the emperor enjoyed the privileges, and suffered from the weaknesses of his position. He had the power of the sword behind him; but he became more and more liable to be deposed, and to be replaced by a new commander, at the will of those who bore the sword in his service.

The period which is marked by the reigns of Diocletian and Constantine (A.D. 284–337) marks a great transformation in the character of the empire. The old dyarchy, under which the emperor might still be regarded as an official of the *respublica Romana,* passed into a new monarchy, in which all political power became, as it were, the private property of the monarch. There was now no distinction of provinces. The old public aerarium which had survived the republic, became merely a municipal treasury: the *fiscus* of the emperor became the exchequer of the empire. The officers of the emperor's *praetorium,* or bodyguard, are made the great officers of state; his private council becomes the public consistory, or supreme court of appeal; and the *comites* of his court are also the administrators of his empire. "All is in him, and all comes from him," as our own year-books say of the mediaeval king: his household, for instance, is not only a household, but also an administration. On the other hand, this unification seems to be accompanied by a new bifurcation. The exigencies of frontier defence had long been drawing the empire towards the troubled East; and this tendency reached its culmination when a new Rome arose by the Bosporus, and Constantinople became the centre of what seemed a second empire in the East (A.D. 324). Particularly after the division of the empire between Arcadius and Honorius in 395 does this bifurcation appear to be marked; and one naturally speaks of the two empires of the West and the East. Yet it cannot be too much emphasized that in reality such language is utterly inexact. The Roman empire was, and always continued to be, ideally one and indivisible. There were two emperors, but one empire—two persons, but one power. The point

is of great importance for the understanding of the whole of the middle ages: there only is, and can be, one empire, though it may, for convenience, be ruled conjointly by two emperors, resident, again for convenience, in two separate capitals. As a matter of fact, the beginning of the residence of an emperor in the East not only did not spell bifurcation actually fostered, but to some extent, the tendency towards unification.[1] It helped forward the transformation of the empire into an absolute and quasi-Asiatic monarchy which reduced all its subjects to a single level of loyal submission: it helped to give the emperor a gorgeous court, marked by all the ceremony and the servility of the East. The deification of the emperor himself dates from the days of Augustus; by the time of Constantine it has infected the court and the government, which are now regarded as in some sense "divine." Each emperor, again, had from the first enjoyed the sacrosanct position which was attached to the tribunate; but now his palace, his chamber, his charities, his letters, are all "sacred," and one might almost speak in advance of a "Holy Roman empire."

Influence of Christianity.—But there is one factor, the greatest of all, which still remains to be added, before we have counted the sum of the forces that made the world think in terms of empire for centuries to come; and that is the reception of Christianity into the Roman empire by Constantine. That reception added a new sanction to the existence of the empire and the position of the emperor. The empire, already one and indivisible in its aspect of a political society, was welded still more firmly together when it was informed and permeated by a common Christianity, and unified by the force of a spiritual bond. The empire was now the church; it was now indeed indestructible, for, if it perished as an empire, it would live as a church. But the church made it certain that it would not perish, even as an empire, for many centuries to come. On the one hand the church thought in terms of empire, and taught the millions of its disciples (including the barbarians themselves) to think in the same terms. No other political conception—no conception of a πόλις or of a nation—was any longer possible. When the church gained its hold of the Roman world, the empire, as it has been well said, was already "not only a government, but a fashion of conceiving the world": it had stood for three centuries; and no man could think of any other form of political association. Moreover, the gospel of St. Paul—that there is *one* church, whereof Christ is the Head, and we are all members—could not but reinforce, in the minds of all Christians, the conception of a necessary political unity of all the world under a single head. *Una Chiesa in uno Stato*—such, then, was the theory of the church. But not only did the church perpetuate the conception of empire by making it a part of its own theory of the world: it perpetuated that conception equally by materializing it in its own organization of itself. Growing up under the shadow of the empire, the church too became an empire, as the empire had become a church. As it took over something of the old pagan ceremonial, so it took over much of the old secular organization. The pope borrowed his title of *pontifex maximus* from the emperor: what is far more, he made himself gradually, and in the course of centuries, the caesar and imperator of the church. The offices and the dioceses of the church are parallel to the offices and dioceses of the Diocletian empire: the whole spirit of orderly hierarchy and regular organization, which breathes in the Roman Church, is the heritage of ancient Rome. The Donation of Constantine is a forgery; but it expresses a great truth when it represents Constantine as giving to the pope the imperial palace and insignia, and to the clergy the ornaments of the imperial army (*see* DONATION OF CONSTANTINE).

Barbarian Invasions.—Upon this world, informed by these ideas, there finally descended, in the 5th century, the avalanche of barbaric invasion. Its impact seemed to split the empire into fragmentary kingdoms; yet it left the Universal Church intact, and with it the conception of empire. With that conception, indeed, the barbarians had already been for centuries familiar: service in Roman armies, and settlement in Roman territories, had made the Roman empire for them, as much as for the civilized provincial, part of the order of the world. One of the barbarian invaders, Odoacer (Odovakar), might seem, in 476, to have swept away the empire from the West, when he commanded the abdication of Romulus Augustulus; and the date 476 has indeed been generally emphasized as marking "the fall of the Western empire." Other invaders, again, men like the Frank Clovis or the great Ostrogoth Theodoric, might seem, in succeeding years, to have completed the work of Odoacer, and to have shattered the sorry scheme of the later empire by remoulding it into national kingdoms. *De facto,* there is some truth in such a view: *de jure,* there is none. All that Odoacer did was to abolish one of the two joint rulers of the indivisible empire, and to make the remaining ruler at Constantinople sole emperor from the Bosporus to the pillars of Hercules. He abolished the dual sovereignty which had been inaugurated by Diocletian, and returned to the unity of the empire in the days of Marcus Aurelius. He did not abolish the Roman empire in the West: he only abolished its separate ruler, and, leaving the empire itself subsisting, under the sway (nominal, it is true, but none the less acknowledged) of the emperor resident at Constantinople, he claimed to act as his vicar, under the name of patrician, in the administration of the Italian provinces (*see* Bryce, *Holy Roman Empire,* p. 25, note *u,* in the edition of 1904). As Odoacer thus fitted himself into the scheme of empire, so did both Clovis and Theodoric. They did not claim to be emperors (that was reserved for Charlemagne): they claimed to be the vicars and lieutenants of the empire. Theodoric spoke of himself to Zeno as *imperio vestro famulans;* he left justice and administration in Roman hands, and maintained two annual consuls in Rome. Clovis received the title of consul from Anastasius; the Visigothic kings of Spain (like the kings of the savage Lombards) styled themselves Flavii, and permitted the cities of their eastern coast to send tribute to Constantinople. Yet it must be admitted that, as a matter of fact, this adhesion of the new barbaric kings to the empire was little more than a form. The empire maintained its ideal unity by treating them as its vicars; but they themselves were forming separate and independent kingdoms within its borders. The Italy of the Ostrogoths cannot have belonged, in any real sense, to the empire; otherwise Justinian would never have needed to attempt its reconquest. And in the 7th and 8th centuries the form of adhesion itself decayed: the emperor was retiring upon the Greek world of the East, and the German conquerors, settled within their kingdoms, lost the width of outlook of their old migratory days.

The Church and the Empire.—It is here that the action of the church becomes of supreme importance. The church had not ceased to believe in the continuous life of the empire. The fathers had taught that when the cycle of empires was finally ended by the disappearance of the empire of Rome, the days of Antichrist would dawn; and, since Antichrist was not yet come, the church believed that the empire still lived, and would continue to live till his coming. Meanwhile the Eastern emperor, ever since Justinian's reconquest of Italy, had been able to maintain some hold on the centre of Italy; and Rome itself, the seat of the head of the church, still ranked as one of the cities under his sway. The imperialist theory of the church found its satisfaction in this connection of its head with Constantinople; and as long as this connection continued to satisfy the church, there was little prospect of any change. For many years after their invasion of 568, the pressure which the Lombards maintained on central Italy, from their kingdom in the valley of the Po, kept the popes steadily faithful to the emperor of the East and his representative in Italy, the exarch of Ravenna. But it was not in the nature of things that such fidelity should continue unimpaired. The development of the East and the West could not but proceed along constantly diverging lines, until the point was reached when their connection must snap. On the one hand, the development of the West set towards the increase of the powers of the bishop of

[1] Bryce points out, with much subtlety and truth, that the rise of a second Rome in the East not only helped to perpetuate the empire by providing a new centre which would take the place of Rome when Rome fell, but also tended to make it more universal; "for, having lost its local centre, it subsisted no longer by historic right only, but, so to speak, naturally, as a part of an order of things which a change in external conditions seemed incapable of disturbing." (*Holy Roman Empire,* p. 8 of the edition of 1904.)

Rome until he reached a height at which subjection to the emperor at Constantinople became impossible. Residence in Rome, the old seat of empire, had in itself given him a great prestige; and to this prestige St. Gregory (pope from 590 to 604) had added in a number of ways. He was one of the fathers of the church, and turned its theology into the channels in which it was to flow for centuries; he had acquired for his church the great spiritual colony of England by the mission of St. Augustine; he had been the protector of Italy against the Lombards. As the popes thus became more and more spiritual emperors of the West, they found themselves less and less able to remain the subjects of the lay emperor of the East. Meanwhile the emperors of the East were led to interfere in ecclesiastical affairs in a manner which the popes and the Western church refused to tolerate. Brought into contact with the pure monotheism of Mohammedanism, Leo the Isaurian (718–741) was stimulated into a crusade against image-worship, in order to remove from the Christian Church the charge of idolatry. The West clung to its images: the popes revolted against Leo's decrees; and the breach rapidly became irreparable. As the hold of the Eastern emperor on central Italy began to be shaken, the popes may have begun to cherish the hope of becoming their successors and of founding a temporal dominion; and that hope can only have contributed to the final dissolution of their connection with the Eastern empire.

Thus, in the course of the 8th century, the empire, *as represented by the emperors at Constantinople*, had begun to fade utterly out of the West. It had been forgotten by lay sovereigns; it was being abandoned by the pope, who had been its chosen apostle. But it did not follow that, because the Eastern emperor ceased to be the representative of the empire for the West, the conception of empire itself had also passed away from it. The popes abandoned only the representative; they did not abandon the conception. If they had abandoned the conception, they would have abandoned the idea that there was an order of the world; they would have committed themselves to a belief in the coming of Antichrist. The conception of the world as a single empire-church remained; and what had to be found was a new representative of one of the two sides of that conception. For a brief time, it would seem, the pope himself cherished the idea of becoming, in his own person, the successor of the ancient Caesars in their own old capital. By the aid of the Frankish kings, he had been able to stop the Lombards from acquiring the succession to the derelict territories of the Eastern emperor in Italy (from which their last exarch had fled overseas in 752), and he had become the temporal sovereign of those territories. Successor to the Eastern emperor in central Italy, why should he not also become his successor as representative of the empire—all the more, since he was the head of the church, which was coextensive with the empire? Some such hope seems to inspire the Donation of Constantine, a document forged between 754 and 774, in which Constantine is represented as having conferred on Silvester I. the imperial palace and insignia, and therewith *omnes Italiae seu occidentalium regionum provincias loca et civitates.* But the hope, if it ever was cherished, proved to be futile. The popes had not the material force at their command which would have made them adequate to the position. The strong arm of the Frankish kings had alone delivered them from the Lombards: the same strong arm, they found, was needed to deliver them from the wild nobility of their own city. So they turned to the power which was strong enough to undertake the task which they could not themselves attempt, and they invited the Frankish king to become the representative of the imperial conception they cherished.[1] In the year 800 central Italy ceased to date its documents by the regnal years of the Eastern emperors; for Charlemagne was crowned emperor in their stead.

Coronation of Charlemagne as Emperor of the West.—The king of the Franks was well fitted for the position which he was chosen to fill. He was king of a stock which had been from the first Athanasian, and had never been tainted, like most of the Germanic tribes, by the adoption of Arian tenets. His grandfather, Charles Martel, had saved Europe from the danger of a Mohammedan conquest by his victory at Poitiers (732); his father, Pippin the Short, had helped the English missionary Boniface to achieve the conversion of Germany. The popes themselves had again and again turned to the Frankish rulers for support in the course of the 8th century. Gregory III., involved in bitter hostilities with the iconoclastic reformers of the East, appealed to Charles Martel for aid, and even offered the king, it is said, the titles of consul and patrician. Zacharias pronounced the deposition of the last of the Merovingian *rois fainéants,* and gave to Pippin, their "mayor of the palace," the title of king (751); while his successor Stephen II., hard pressed by the Lombards, who were eager to replace the Eastern emperors in the possession of central Italy, not only asked and received the aid of the new king, but also acquired, in virtue of Pippin's donation (754), the disputed exarchate itself. Thus was laid the foundation of the states of the church; and the grateful pope rewarded the donation by the gift of the title of *patricius Romanorum,* which conferred on its recipient the duty and the privilege of protecting the Roman Church, along with some undefined measure of authority in Rome itself.[1] Again, in 773, Pope Adrian I. had to appeal to Charles, the successor of Pippin, against the aggressions of the last of the Lombard kings; and in 774 Charles conquered the Lombard kingdom, and himself assumed its iron crown. Thus by the end of the 8th century the Frankish king stood on the very steps of the imperial throne. He ruled a realm which extended from the Pyrenees to the Harz, and from Hamburg to Rome—a realm which might be regarded as in itself a *de facto* empire. He bore the title of *patricius,* and he had shown that he did not bear it in vain by his vigorous defence of the papacy in 774. Here there stood, ready to hand, a natural representative of the conception of empire; and Leo III., finding that he needed the aid of Charlemagne to maintain himself against his own Romans, crowned him emperor at St. Peter's, on Christmas Day, 800.

The coronation of Charlemagne in 800 marks the coalescence into a single unity of two facts, or rather, more strictly speaking, of a fact and a theory. The fact is German and secular: it is the wide *de facto* empire, which the Frankish sword had conquered, and Frankish policy had organized as a single whole. The theory is Latin and ecclesiastical: it is a theory of the necessary political unity of the world, and its necessary representation in the person of an emperor—a theory half springing from the unity of the old Roman empire, and half derived from the unity of the Christian Church as conceived in the New Testament. If we seek for the force which caused this fact and this theory to coalesce in the Carolingian empire, we can only answer—the papacy. The idea of empire was in the church; and the head of the church translated this idea into fact. If, however, we seek to conceive the event of 800 from a political or legal point of view, and to determine the residence of the right of constituting an emperor, we at once drift into the fogs of centuries of controversy. Three answers are possible from three points of view; and all have their truth, according to the point of view. From the ecclesiastical point of view, the right resides with the pope. This theory was not promulgated (indeed no theory was promulgated) until the struggles of papacy and empire in the course of the middle ages; but by the time of Innocent III. it was becoming an established doctrine that a *translatio Imperii* took place in 800, whereby the pope transferred the Roman empire from the Greeks to the Germans in the person of the magnificent Charles.[2] One can only say that, as a matter of fact, the popes ceased to recognize the Eastern

[1]According to the view here followed, the church was the ark in which the conception of empire was saved during the dark ages between 600 and 800. Some influence should perhaps also be assigned to Roman law, which continued to be administered during these centuries, especially in the towns, and maintained the imperial tradition. But the influence of the church is the essential fact.

[1]In the 5th century the title *patricius* came to attach particularly to the head of the Roman army (*magister utriusque militiae*)—to men like Aetius and Ricimer, to made and unmade emperors (*cf.* Mommsen, *Gesammelte Schriften,* iv. 537, 545 *sqq.*). Later it had been borne by the Greek exarchs of Ravenna. The concession to Pippin of this great title makes him military head of the Western empire, in the sense in which the title was used in the 5th century; it makes him representative of the empire for Italy, in the sense in which it had been used of the exarchs.

[2]*See* the famous bull *Venerabilem* (*Corp. Iur. Canon.* Decr. Greg, i. 6, c. 34).

emperors, and recognized Charles instead, in the year 800; that, again, this recognition alone made Charles emperor, as nothing else could have done; but that no question arose, at the time, of any right of the pope to give the Empire to Charlemagne, for the simple reason that neither of the actors was acting or thinking in a legal spirit. If we now turn to study the point of view of the civil lawyer, inspired by legal ideas, and basing himself on the code of Justinian, we shall find that an emperor must derive his institution and power from a *lex regia* passed by the *populus Romanus;* and such a view, strictly interpreted, will lead us to the conclusion that the citizens of Rome had given the crown to Charlemagne in 800, and continued to bestow it on successive emperors afterwards. There is indeed some speech, in the contemporary accounts of Charlemagne's coronation, of the presence of "ancients among the Romans" and of "the faithful people"; but they are merely present to witness or applaud, and the conception of the Roman people as the source of empire is one that was only championed during the middle ages by antiquarian idealists like Arnold of Brescia and Cola di Rienzi. The *faex Romuli,* a population of lodging-house keepers, living upon pilgrims to the papal court, could hardly be conceived, except by an ardent imagination, as heir to the *Quirites* of the past. Finally, from the point of view of the German tribesman, we must admit that the empire was something which, once received by his king (no matter how), descended in the royal family as an heirloom; or to which (when the kingship became elective) a title was conferred, along with the kingship, by the vote of electors.[1]

But apart from these questions of origin, two difficulties have still to be faced with regard to the nature and position of the Carolingian empire. Did Charlemagne and his successors enter into a new relation with their subjects, in virtue of their coronation? And what was the nature of the relation between the new emperor now established in the West and the old emperor still reigning in the East? It is true that Charlemagne exacted a new oath of allegiance from his subjects after his coronation, and again that he had a revision of all the laws of his dominions made in 802. But the revision did not amount to much in bulk: what there was contained little that was Roman; and, on the whole, it hardly seems probable that Charlemagne entered into any new relation with his subjects. The relation of his empire to the empire in the East is a more difficult and important problem. In 797 the empress Irene had deposed and blinded her son, Constantine VI., and usurped his throne. Now it would seem that Charlemagne, whose thoughts were already set on empire, hoped to depose and succeed Irene, and thus to become the sole representative of the conception of empire, alike in the East and the West. Suddenly there came, in 800, his own coronation as emperor, an act apparently unpremeditated at the moment, taking him by surprise, as one gathers from Einhard's *Vita Karoli,* and interrupting his plans. It left him representative of the empire for the West only, confronting another representative in the East. Such a position he did not desire: there had been a single empire vested in a single person since 476, and he desired that there should still continue to be a single empire, vested only in his own person. He now sought to achieve this unity by a proposal of marriage to Irene. The proposal failed, and he had to content himself with a recognition of his imperial title by the two successors of the empress. This did not, however, mean (at any rate in the issue) that henceforth there were to be two conjoint rulers, amicably ruling a single empire as colleagues in the manner of Arcadius and Honorius. The dual government of a single empire established by Diocletian had finally vanished in 476; and the unity of the empire was now conceived, in the manner common before the days of Diocletian, as demanding a single representative. Henceforth there were two rulers, one at Aix-la-Chapelle and one at Constantinople, each claiming, whatever temporary concessions he might make, to be the sole ruler and representative of the Roman empire. On the one hand, the Western emperors held that, upon the deposition of Constantine VI., Charlemagne had succeeded him, after a slight interval, in the government of the whole empire, both in the East and in the West; on the other hand, the Eastern emperors, in spite of their grudging recognition of Charlemagne at the moment, regarded themselves as the only lawful successors of Constantine VI. in the title of emperor, and viewed the Carolings and their later successors as upstarts and usurpers, with no right to their imperial pretensions. Henceforth two halves confronted one another, each claiming to be the whole; two finite bodies touched, and each yet claimed to be infinite.

[1]Even on this view, an imperial coronation at the hands of the pope was necessary to complete the title; but this was regarded by the Germans (though not by the pope) as a form which necessarily followed.

Character of the Carolingian Empire.—If, as has been suggested, Charlemagne did not enter into any fundamentally new relations with his subjects after his coronation, it follows that the results of his coronation, in the sphere of policy and administration, cannot have been considerable. The empire added a new sanction to a policy and administration already developed. Charlemagne had already showed himself *episcopus episcoporum,* anxious not only to suppress heresy and supervise the clergy within his borders, but also to extend true Christianity outside them, even before the year when his imperial coronation gave him a new title to supreme governorship in all cases ecclesiastical. He had already organized his empire on a new uniform system of counties, and the *missi dominici* were already at work to superintend the action of the counts, even before the *renovatio imperii Romani* came to suggest such uniformity and centralization. Charlemagne had a new title; but his subjects still obeyed the king of the Franks, and lived by Frankish law, in the old fashion. In their eyes, and in the eyes of Charlemagne's own descendants, the empire was something appendant to the kingship of the Franks, which made that kingship unique among others, but did not radically alter its character. True, the kingship might be divided among brothers by the old Germanic custom of partition, while the empire must inhere in one person; but that was the one difference, and the one difficulty—which might easily be solved by attaching the name of emperor to the eldest brother. Such was the conception of the Carolings: such was not, however, the conception of the church. To the popes the empire was a solemn office, to which the kings of the Franks might most naturally be called, in view of their power and the traditions of their house, but which by no means remained in their hands as a personal property. By thus seeking to dissociate the empire from any indissoluble connection with the Carolingian house, the popes were able to save it. Civil wars raged among the descendants of Charlemagne: partitions recurred: the empire was finally dissolved, in the sense that the old realm of Charlemagne fell asunder, in 888. But the empire, as an office, did not perish. During the 9th century the popes had insisted, as each emperor died, that the new emperor needed coronation at their hands: and they had thus kept alive the conception of the empire as an office to which they invited, if they did not appoint, each successive emperor. The quarrels of the Carolingian house helped them to make good their claim. John VIII. was able to select Charles the Bald in preference to other claimants in 875; and before the end of his pontificate he could write that "he who is to be ordained by us to the empire must be by us first and foremost invited and elected." Thus was the unity of the empire preserved, and the conception of a united empire continued, in spite of the eventual dissolution of the realm of Charlemagne. When the Carolingian emperors disappeared, Benedict IV. could crown Louis of Provence (901), and John X. could invite to the vacant throne an Italian potentate like Berengar of Friuli (915); and even when Berengar died in 924, and the empire was vacant of an emperor, they could hold, and hold with truth, that the empire was not dead, but only suspended, until such time as they should invite a new ruler to assume the office.

The German Kingdom and the Empire.—Various causes had contributed to the dissolution of the realm of Charlemagne. Partitions had split it; feudalism had begun to honeycomb it; incessant wars had destroyed its core, the fighting Franks of Austrasia. But, above all, the rise of divisions within the realm, which, whether animated by the spirit of nationality or not, were ultimately destined to develop into nations, had silently under-

mined the structure of Pippin and Charlemagne. Already in 842 the oath of Strasbourg shows us one Caroling king swearing in French and another in German: already in 870 the partition of Mersen shows us the kings of France and Germany dividing the middle kingdom which lay between the two countries by the linguistic frontier of the Meuse and Moselle. The year 888 is the birth-year of modern Europe. France, Germany, Italy, stood distinct as three separate units (with Burgundy and Lorraine as debatable lands) as they were destined to remain for centuries to come. If the conception of empire was still to survive, the pope must ultimately invite the ruler of the strongest of these three units to assume the imperial crown; and this was what happened when in 962 Pope John XII. invited Otto I. of Germany to renew once more the Roman empire. As the strength of the whole Frankish realm had given it the Empire in 800, so did the strength of the East Frankish kingdom, now resting indeed on a Saxon rather than a Frankish basis, bring the empire to its ruler in 962. The centre of political gravity had already been shifting to the east of the Rhine in the course of the 9th century. While the Northmen had carried their arms along the rivers and into the heart of France, Louis the German had consolidated his kingdom in a long reign of 60 years (817–876); and at the end of the 9th century two kings of Germany had already worn the imperial crown. Early in the 10th century the kingship of Germany had come to the vigorous Saxon dukes (919); and strong in their Saxon basis Henry I. and his son Otto had built a realm which, disunited as it was, was far more compact than that which the Carolings of the West ruled from Laon. Henry I. had thought in his later years of going to Rome for the imperial crown: under Otto I. the imperial idea becomes manifest. On the one hand, he established a semi-imperial position in the West: by 946 Louis IV. d'Outremer is his protégé in France, and it is his arms which maintain the young Conrad on his throne in Burgundy. On the other hand, he showed, by his policy towards the German Church, that he was the true heir of the Carolingian traditions. He made churchmen his ministers; he established missionary bishoprics on the Elbe which should spread Christianity among the Wends; and his dearest project was a new archbishopric of Magdeburg. The one thing needful was that he should, like Charlemagne, acquire the throne of Italy; and the disunited condition of that country during the first half of the 10th century made its acquisition not only possible, but almost imperative. Begun in 952, the acquisition was completed ten years later; and all the conditions were now present for Otto's assumption of the imperial throne. He was crowned by John XII. on Candlemas Day 962, and thus was begun the Holy Roman empire, which lasted until 1806.[1]

The Holy Roman Empire.—The same ideas underlay the new empire as had underlain that of Charlemagne, but they were strengthened and reinforced by the fact that they had already found a visible expression before in that earlier empire. Historically, there was the tradition of the old Roman empire, preserved by the church as an idea, and preserved in the church, and its imperial organization, as an actual fact. Ecclesiastically, there was the Pauline conception of a single Christian Church, one in subjection to Christ as its Head, and needing (so men still thought) a secular counterpart of its indivisible unity.[2] To these two sanctions philosophy later added a third; and the doctrine of Realism, that the one universal is the true abiding substance—the doctrine which pervades the *De monarchia* of Dante—reinforced the feeling which demanded that Europe should be conceived as a single political unity. But if the Holy Roman empire of the German nation has the old foundations, it is none the less a thing *sui generis*. Externally, it meant far less than the empire of Charlemagne; it meant simply a union of Germany and northern Italy (to which, after 1032, one must also add Burgundy, though the addition is in reality nominal) under a single rule. Historians of the 19th century, during the years in which the modern German empire was in travail, disputed sorely on the advantages of this union; but whatever its advantages or disadvantages, the fact remains that the union of Teutonic Germany and Latin Italy was, from an external point of view, the essential fact in the structure of the mediaeval empire. Internally, again, the empire of the Ottos and their successors was new and unprecedented. If Latin imperialism had been combined with Frankish tribalism in the empire of Charlemagne, it now met and blended with feudalism. The Holy Roman emperor of the middle ages, as Frederick I. proudly told the Roman envoys, found his senate in the diet of the German baronage, his *equites* in the ranks of the German knights. Feudalism, indeed, came in time to invade the very conception of empire itself. The emperors began to believe that their position of emperor made them feudal overlords of other kings and princes; and they came to be regarded as the topmost summit of the feudal pyramid, from whom kings held their kingdoms, while they themselves held directly of God. In this way the old conception of the world as a single political society entered upon a new phase: but the translation of that conception into feudal terms, which might have made Diocletian gasp, only gave it the greater hold on the feudal society of the middle ages. Yet in one way the feudal conception was a source of weakness to the empire; for the popes, from the middle of the 12th century onwards, began to claim for themselves a feudal overlordship of the world, and to regard the emperor as the chief of their vassals. The theory of the *Translatio* buttressed their claim to be overlords of the empire; and the emperors found that their very duty to defend the papacy made them appear as its vassals—for was not the *advocatus* who defended the lands of an abbey or church its tenant by feudal service, and was not the emperor an "advocate" of the papacy and its patrimony in central Italy?

The Empire and the Papacy.—The relation of the empire to the papacy is indeed the cardinal fact in its history for the three centuries which followed the coronation of Otto I. (962–1250). For a century (962–1076) the relation was one of amity. The pope and the emperor stood as co-ordinate sovereigns, ruling together the commonwealth of Europe.[1] If either stood before the other, the emperor stood before the pope. The Romans had sworn to Otto I. that they would never elect or ordain a pope without his consent; and the rights over papal elections conceived to belong to the office of *patricius*, which they generally held, enabled the emperors, upon occasion, to nominate the pope of their choice. The partnership of Otto III., son of a Byzantine princess, and his nominee Silvester II. (the famous Gerbert, who had been *scholasticus* of the chapter school of Reims) forms a remarkable page in the annals of empire and papacy. Otto, once the pupil of Silvester in classical studies, and taught by his mother the traditions of the Byzantine empire, dreamed of renewing the empire of Constantine, with Rome itself for its centre; and this antiquarian idealism (which Arnold of Brescia and Cola di Rienzi were afterwards, though with some difference of aim, to share) was encouraged in his pupil by the pope. Tradition afterwards ascribed to the two the first project of a crusade, and the institution of the seven electors: in truth their faces were turned to the past rather than to the future, and they sought not to create, but to renovate. The dream of restoring the age of Constantine passed

[1] It is a curious fact that imperial titles (*imperator* and *basileus*) are used in the Anglo-Saxon documents of the 10th century, about the time of Otto I.'s coronation. Edred, for instance (946–955), is "imperator" and "basileus Anglorum huiusque insulae barbarorum": Edgar is "totius Albionis imperator Augustus" (*cf.* Stubbs, *Const. Hist.* i., c. vii. § 71). These titles partly show the turgidity of English Latinity in the 10th century, and partly indicate the quasi-imperial position held by the Wessex kings after the reconquest of the Dane-law. But there seems to be no real ground for Freeman's view (*Norman Conquest*, i. 548 *sqq.*) that England was regarded as a third empire, side by side with the other empires of Western and Eastern Europe.

[2] It is in virtue of this aspect that the Empire is holy. The term *sacrum imperium* seems to have been first used about the time of Frederick I., when the emperors were anxious to magnify the sanctity of their office in answer to papal opposition. The emperor himself (*see* under EMPEROR) was always regarded, and at his coronation treated, as a *persona ecclesiastica*.

[1] The emperor claimed suzerainty over the greater part of Europe at various dates. Hungary and Poland, France and Spain, the Scandinavian peninsula, the British Isles, were all claimed for the empire at different times (*see* Bryce, *Holy Roman Empire*, c. xii.). The "effective" empire, if indeed it may be called effective, embraced only Germany, Burgundy and the *regnum Italiae* (the old Lombard kingdom in the valley of the Po).

with the premature death of Otto; and after the death of Silvester II. the papacy was degraded into an appendage of the Tusculan family. From that degradation the church was rescued by Henry III. (the second emperor of the new Salian house, which reigned from 1024–1125), when in 1046 he caused the deposition of several popes, and afterwards filled the papal chair with his own nominees; but it was rescued more effectually by itself, when in 1059 the celebrated bull *In nomine Domini* of Nicholas II. reserved the right of electing the popes to the college of cardinals (*see* CONCLAVE). A new era of the papacy begins with the decree, and that era found its exponent in Hildebrand. If under Henry III. the empire stands in many respects at its zenith, and the emperor nominates to the Papacy, it sinks, under Henry IV., almost to the nadir of its fortunes, and a pope attempts, with no little success, to fight and defeat an emperor.

The rise of the papacy, which the action of Henry III. in 1046 had helped to begin, and the bull of 1059 had greatly promoted, was ultimately due to one of those movements of ecclesiastical revival which recur in the history of the Catholic Church. The aim of that movement was to separate the church from the world, and thus to make it independent of the laity and the lay power; and it sought to realize its aim first by the prohibition of clerical marriage and simony, and ultimately by the prohibition of lay investiture. A decree of Gregory VII. in 1075 forbade emperor, king or prince to "presume to give investiture of bishoprics," under pain of excommunication; and Henry IV., contravening the decree, fell under the penalty, and the War of Investitures began (1076–1122). Whether or not Henry humiliated himself at Canossa (and the opinion of German historians now inclines to regard the traditional account as exaggerated), the empire certainly suffered in his reign a great loss of prestige. The emperor lost his hold over Germany, where the aid of the pope strengthened the hands of the discontented nobility: he lost his hold over Italy, where the Lombard towns gradually acquired municipal independence, and the donation of the Countess Matilda gave the popes the germ of a new and stronger *dominium temporale*. The First Crusade came, but the emperor, its natural leader, could not lead it; and the centre of learning and civilization, in the course of the 50 years' War of Investitures, gradually shifted to France. The struggle was finally ended by a compromise—the Concordat of Worms—in 1122; but the papacy, which had fought the long War of Investitures and inspired the First Crusade, was a far greater power than it had been at the beginning of the struggle, and the emperor, shaken in his hold on Germany and Italy, had lost both power and prestige (*see* INVESTITURE). It is significant that a theory of the feudal subjection of the emperor to the pope, foreshadowed in the pontificate of Innocent II., and definitely enunciated by the envoys of Adrian IV. at the diet of Besançon in 1157, now begins to arise. The popes, who had called the emperors to the heads of the European commonwealth in 800 and again in 962, begin to vindicate that headship for themselves. Gregory VII. had already claimed that the pope stood to the emperor as the sun to the moon; and gradually the old idea of co-ordination disappeared in a new view of the subordination of the empire to the papal *plenitudo potestatis*. The claim of ecclesiastical independence made in the middle of the 11th century was rapidly becoming a claim of ecclesiastical supremacy in the middle of the 12th: the imperial claim to nominate popes, which had lasted till 1059, was turning into the papal claim to nominate emperors. Yet at this very time a new period of splendour dawned for the empire; and the rule of the three Hohenstaufen emperors, Frederick I., Henry VI. and Frederick II. (1152–1250), marks the period of its history which attracts most sympathy and admiration.

The Hohenstaufen Emperors.—Frederick I. regained a new strength in Germany, partly because he united in his veins the blood of the two great contending families, the Welfs and the Waiblingens; partly because he had acquired large patrimonial possessions in Swabia, which took the place of the lost Saxon demesne; partly because he had a greater control over the German episcopate than his predecessors had enjoyed for many years past. At the same time the revival of interest in the study of Roman law gave the emperor, as source and centre of that law, a new dignity and prestige, particularly in Italy, the home and hearth of the revival. Confident in this new strength, he attempted to vindicate his claims on Italy, and sought, by uniting the two under his sway, to inspire with new life the old Ottonian empire. He failed to crush Lombard municipal independence: defeated at Legnano in 1176, he had to recognize his defeat at the treaty of Constance in 1183. He failed to acquire control over the papacy: a new struggle of empire and papacy, begun in the pontificate of Adrian IV. on the question of control over Rome, and continued in the pontificate of Alexander III., because Frederick had recognized an anti-pope, ended in the emperor's recognition of his defeat at Venice in 1177. The one success was the acquisition of the Norman kingdom of Sicily for his son and successor Henry VI., who was married to its heiress, Constance. But the one success of Frederick's Italian policy proved the ruin of his house in the reign of his grandson Frederick II. On the one hand, the possession of Sicily induced Frederick II. to neglect Germany; and by two documents, one of 1220 and one of 1231, he practically abdicated his sovereign powers to the German princes in order to conciliate their support for his Italian policy. On the other hand, the possession of Sicily involved him in the third great struggle of empire and papacy. Strong in his Sicilian kingdom in the south, and seeking, like his grandfather, to establish his power in Lombardy, Frederick practically aimed at the unification of Italy, a policy which threatened to engulf the states of the church and to reduce the papacy to impotence. The popes excommunicated the emperor: they aided the Lombard towns to maintain their independence; finally, after Frederick's death (1250), they summoned Charles of Anjou into Sicily to exterminate his house. By 1268 he had done his work, and the mediaeval empire was practically at an end. When Rudolph of Habsburg succeeded in 1273, he was only the head of a federation of princes in Germany, while in Italy he abandoned all claims over the centre and south, and only retained titular rights in the Lombard plain.

Thus ended the first great chapter in the history of the Holy Roman Empire which Otto had founded in 962. In those three centuries the great fact had been its relation to the papacy: in the last two of those three centuries the relation had been one of enmity. The basis of the enmity had been the papal claim to supreme headship of Latin Christianity, and to an independent temporal demesne in Italy as the condition of that headship. Because they desired supreme headship, the popes had sought to reduce the emperor's headship to something lower than, and dependent upon, their own: because they desired a temporal demesne, they had sought to expel him from Italy, since any imperial hold on Italy threatened their independence. They had succeeded in defeating the empire, but they had also diminished the papacy; for the French aid which they had invoked against the Hohenstaufen developed, within 50 years of the fall of that house, into French control, and the captivity at Avignon (1308–78) was the logical result of the final victory of Charles of Anjou at Tagliacozzo. The struggle seemed to have ended in nothing but the exhaustion of both combatants. Yet in many respects it had in reality made for progress. It had set men thinking of the respective limits of church and state, as the many *libelli de lite imperatorum et pontificum* show; and from that thought had issued a new conception of the state, as existing in its own right and supreme in its own sphere, a conception which is the necessary basis of the modern nation-state. If it had dislocated Germany into a number of territorial principalities, it had produced a college of electors to represent the cause of unity: if it had helped to prevent the unification of Italy, and had left to Italy the fatal legacy of Guelph and Ghibelline feuds, it had equally helped to produce Italian municipal independence.

The Empire from the Election of Rudolph of Habsburg, 1273.—A new chapter of the history of the empire fills the three centuries from 1273–1556—from the accession of Rudolph of Habsburg to the abdication of Charles V. Italy was now lost: the empire had now no peculiar connection with Rome, and far less touch with the papacy. A new Germany had risen. The extinction of several royal stocks, and the nomination of anti-kings in the

course of civil wars, had made the monarchy elective, and raised to the side of the emperor a college of electors (*see* ELECTORS), which appears as definitely established soon after 1250. With Italy lost, and Germany thus transmuted, why should the empire have still continued to exist? In the first place, it continued to exist because the Germans still found a king necessary, and because, the German king having been called for three centuries emperor, it seemed necessary that he should still continue to bear the name. In this sense the empire existed as the presidency of a Germanic confederation, and as something analogous to the German empire between 1870 and 1918, with the one great difference that the Hohenzollerns derived from Prussia a strength which enabled them to make their imperial position a reality, while no Luxembourg of Habsburg was able to make his imperial position otherwise than honorary and nominal. In the second place, it continued to exist because the conception of the unity of western Europe still lingered, and was still conceived to need an exponent. In this sense the empire existed as a presidency, still more honorary and still more nominal, of the nations of western Europe. In both capacities the emperor may be said to have existed because he was a legal necessity—because, in Germany, he was necessary for the investiture of princes with their principalities, and because, in Europe, he was necessary, as the source of all rights, to bestow crowns upon would-be kings, or to act as the head of the great orders of chivalry, or to give patents to notaries. With the history of the empire regarded as a German confederation we are not here concerned. The reigns of the Habsburg, Luxembourg and Wittelsbach emperors belong to the history of Germany. Yet two of these emperors, Henry VII. and Louis IV., should not pass without notice, the one for his own sake, the other for the sake of his adherents, and both because, by interfering in Italy, and by coming into conflict with the papacy, they brought once more into prominence the European aspect of the empire.

Henry VII., the contemporary and the hero of Dante, descended into Italy in 1310, partly because he had no power and no occupation in Germany, partly because he was deeply imbued with the sense of his imperial dignity. Coming as a peacemaker and mediator, he was driven by Guelph opposition into a Ghibelline rôle; and he came into conflict with Clement V., the first of the Avignonese popes, who under the pressure of France attempted to enforce upon Henry a recognition of his feudal subjection. Henry asserted his independence: he claimed Rome for his capital, and the lordship of the world for his right; but, just as a struggle seemed impending, he died, in 1313. During the reign of his successor, Louis IV., the struggle came. Louis had been excommunicated by John XXII. in 1324 for acting as emperor before he had received papal recognition. None the less, in 1328, he came to Rome for his coronation. He had gathered round him strange allies; on the one hand, the more advanced Franciscans, apostles of the cause of clerical disendowment, and inimical to a wealthy papacy; on the other hand, jurists like Marsilius of Padua and John of Jandun, who brought to the cause of Louis the spirit and the doctrines which had already been used in the struggle between Boniface VIII. and Philip IV. of France. Marsilius in particular, in a treatise called the *Defensor Pacis,* insisted on the majesty of the lay state, and even on its superiority to the church. Perhaps it was Marsilius, learned as he was in Roman law, and remembering the *lex regia* by which the Roman people had of old conferred its power on the emperor, who suggested to Louis the policy, which he followed, of receiving the imperial crown by the decree and at the hands of the Roman people. The policy was remarkable: Louis embraced an alliance which Frederick Barbarossa had spurned, and recognized the mediaeval Romans as the source of imperial power. Not less remarkable was the new attitude of the German electors, who for the first time supported an emperor against the pope, because they now felt menaced in their own electoral rights; and the one permanent result which finally flowed from the struggle was the enunciation and definition of the rights and privileges of the electors in the Golden Bull of 1356 (*see* GOLDEN BULL).

In this struggle with the papacy the empire had shown something of its old universal aspect. It had come into connection with Italy, and into close connection with Rome: it had enlisted in defence of its rights at once an Italian like Marsilius and an Englishman like Ockham. The same universal aspect appeared once more in the age of the conciliar movement, at the beginning of the 15th century. One of the essential duties of the emperor, as defender of the church, was to help the assembling and the deliberations of general councils of the church. This was the duty discharged by Sigismund, when he forced John XXIII. to summon a council at Constance in 1414, and sought, though in vain, to guide its deliberations. The journey which Sigismund undertook in the interests of the council (1415–17) is particularly noteworthy. He sought to make peace throughout western Europe, acting as international arbitrator—in virtue of his presidency of western Europe—between England and France, between Burgundians and Armagnacs; but he failed in his aim, and when he returned to the council, it was only to witness the defeat of the party of reform which he championed. National feeling and national antipathies proved too strong for Sigismund's attempt to revive the mediaeval empire for the purposes of international arbitration; the same feeling, the same antipathies, made inevitable the failure of the council itself, in which western Europe had sought to meet once more as a single religious commonwealth. Early in the 15th century, therefore, the conception of the unity of western Europe, as a single empire-church, was already waning in both its aspects. The unity of the Church Universal was dissolving, and the conception of the nation-church arising (as the separate concordats granted by Martin V. to the different nations prove); while the unity of the empire was proved a dream by the powerlessness of the emperor in the face of the struggle of England and France.

Influence of the Reformation.—Renaissance and Reformation combined to complete the fall which the failure of Sigismund to guide the conciliar movement had already foreshadowed. The Renaissance, revolting against the mediaevalism of the *studium,* and not sparing even the *sacerdotium* of the middle ages, had little respect for the mediaeval *imperium;* and, going back to pure Latin and original Greek, it went back beyond even the classical empire to find its ideals and inspirations. But it is the coming of the Reformation, and with it of the nation-church, which finally marks the epoch at which the last vestige of the old conception of the political unity of the world disappears before the nation-state. Externally indeed it seemed, at the time of the Reformation, as if the old empire had been revived in the person of Charles V., who owned territories as vast as those of Charlemagne. But Charles's dominions were a dynastic agglomeration, knit together by no vivifying conception; and, though Charles was a champion of the one Catholic Church against the Reformation, he did not in any way seek to revive the power of the mediaeval empire. Meanwhile the reforming monarchs, while they cast off the Roman Church, cast off with it the Roman empire. Henry VIII. declared himself free, not only of the pope, but of all other foreign power; and not only so, but as he sought to take the place of the pope with regard to his own church, so he sought to take the place of the emperor with regard to his kingdom, and spoke of his "imperial" crown, a style which recurs in later Tudor reigns. The conception of one empire passed out of Europe, or, if it remained, it remained only in an honorary precedence accorded by other sovereigns to the king of Germany, who still entitled himself emperor. In Germany itself the honorary presidency which the emperor enjoyed over the princes came to mean still less than before, when religious differences divided the country, and the principle of *cujus regio ejus religio* accentuated the local autonomy of the prince. When Charles abdicated in 1556, the change which the accession of Rudolph of Habsburg had already marked was complete: there was no empire except in Germany, and in Germany the empire was nothing more than a convenient legal conception. The Reformation, by sweeping away the spiritual unity of western Christendom, had swept away any real conception of its political unity, and with that conception it had swept away the empire; while it had also, by splitting Germany into two religious camps, and making the emperor at the most the head of a religious faction, dissipated the last vestiges of a real empire in the

country which had, since 962, been its peculiar home.

From 1556 to 1806 the empire means a loose federation of the different princes of Germany, lay and ecclesiastical, under the presidency, elective in theory but hereditary in practice, of the house of Habsburg. The dissolution of the Holy Roman empire into this loose federation had already been anticipated by the concessions made to the princes by Frederick II. in 1220 and 1231; but the final organization of Germany on federal lines was only attained in the treaty of Westphalia of 1648. The attempt of Ferdinand II., in the course of the Thirty Years' War, to assert a practically monarchical authority over the princes of Germany, only led to the regular vindication by the princes of their own monarchical authority. The emperor, who had tried in the 15th century to be the international authority of all Europe, now sank to the position of less than inter-state arbitrator in Germany. That the empire and the emperor were retained at all, when the princes became so many independent sovereigns, was due partly to a lingering sense of quasi-national sentiment for a *magni nominis umbra*, partly to the need of some authority which should combine in one body principalities of very different sizes and strengths, and should protect the weak from the strong, and all from France. But this authority only found its *symbol* in the emperor. Such real federal authority as there was remained with the diet, a congress of sovereign princes through their accredited representatives; and the emperor's sole rights, as emperor, were those of granting titles and confirming tolls. The Habsburgs, emperors in each successive generation, never pursued an imperial, but always a dynastic policy; and they were perfectly ready to sacrifice to the aggrandizement of their house the honour of the empire, as when they ceded Lorraine to France in return for Tuscany (1735).

End of the Holy Roman Empire.—It needed the cataclysm of the French Revolution finally to overthrow the empire. Throughout the 18th century it lasted, a thing of long-winded protocols and never-ending lawsuits, "neither Holy, nor Roman, nor an Empire." But with Napoleon came its destroyer. As far back as the end of the 13th century, French kings had been scheming to annex the title or at any rate absorb the territories of the empire: at the beginning of the 19th century the annexation of the title by Napoleon seemed very imminent. Posing as the New Charlemagne ("because, like Charlemagne, I unite the crown of France to that of the Lombards, and my Empire marches with the East"), he resolved in 1806, during the dissolution and recomposition of Germany which followed the peace of Lunéville, to oust Francis II. from his title, and to make the Holy Roman empire part and parcel of the "Napoleonic idea." He was anticipated, however, by the prompt action of the proud Habsburg, who was equally resolved that no other should wear the crown which he himself was powerless to defend, and accordingly, on Aug. 6, 1806, Francis resigned the imperial dignity. So perished the empire. Out of its ashes sprang the Austrian empire, for Francis, in 1804, partly to counter Napoleon's assumption of the title of Emperor of the French, partly to prepare for the impending dissolution of the old empire, had assumed the title of "Hereditary Emperor of Austria."

General Influence of the Empire.—What had been the results of the Holy Roman empire, in the course of its long history, upon Germany and upon Europe? It has been a vexed question among German historians, whether or not the Empire ruined Germany. Some have argued that it diverted the attention of the German kings from their own country to Italy, and that, by bringing them into conflict with the popes, and by thus strengthening the hands of their rebellious baronage with a papal alliance, it prevented the development of a national monarchy in Germany, such as other sovereigns of western Europe were able to found. Others again have emphasized the racial division of Saxon and Frank, of High German and Low German, as the real cause of the failure of Germany to grow into a united national whole: they have sought to ascribe to the influence of the empire such unity as was achieved; and they have attributed the learning, the trade, the pre-eminence of mediaeval Germany to the Italian connection and the prestige which the empire brought. It is difficult to pronounce on either side; but it is possible that the old localism and individualism which characterized the early German, and had never, on German soil, been combined with and counteracted by a large measure of Roman population and Roman civilization, as they were in Gaul and Spain, would in any case have continued to divide and disturb Germany till late in her history, even if the empire had never come to reside within her borders. On the larger question of the influence of the empire on Europe at large, all that can here be said is that Europe was all the better for the survival of some idea of unity. An empire which represented, as a Holy empire, the unity of all the faithful in one body—an empire which, as a Roman empire, represented with an unbroken continuity the order of Roman administration and law—such an empire could not but make for the betterment of the world. It was not an empire resting on force, a military empire; it was not, as in modern times empires have sometimes been, an autocracy warranted and stamped by the plébiscite of the mob. It was an empire resting neither on the sword nor on the ballot-box, but on two great ideas, taught by the clergy and received by the laity, that all believers in Christ form one body politic, and that the one model and type for the organization of that body is to be found in the past of Rome. It was indeed the weakness of the empire that its roots were only the thoughts of men; for the lack of material force, from which it always suffered, hindered it from doing work it might well have done—the work, for instance, of international arbitration. Yet, on the other hand, it was the strength and glory of the empire that it lived, all through the middle ages, an unconquerable idea of the mind of man. Because it was a being of their thought, it stirred men to reflection: the empire, particularly in its clash with the papacy, produced a political consciousness and a political speculation reflected for us in the writings of mediaeval schoolmen and lawyers, not least in those of Dante and Marsilius of Padua. Roman, it perpetuated the greatest monument of Roman thought—that ordered scheme of law, which either became, as in England, the model for the building of a native system, or, as in Germany from the end of the 15th century onwards, was received in its integrity and administered in the courts. Holy, it fortified and consolidated Christian thought, by giving a visible expression to the kingdom of God upon earth; and not only so, but it maintained, however imperfectly, some idea of international obligation, and some conception of a commonwealth of Europe.

The Holy Roman empire of western Europe had in its own day a contemporary and a rival—that East Roman empire of which we have already spoken. From Arcadius to John Palaeologus, from A.D. 395 to 1453, the Roman empire was continued at Constantinople—not as a theory and an idea, but as a simple and daily reality of politics and administration. In one sense the East Roman empire was more lineally and really Roman than the West: it was absolutely continuous from ancient times. In another sense the Western empire was the more Roman; for its capital—in theory at least—was Rome itself, and the Roman Church stood by its side, while Constantinople was Hellenic and even Oriental. Between the two empires there was fixed an impassable gulf. They were divided by deep differences of thought and temper, which appeared more particularly in the sphere of religion, and expressed themselves in the cleavage between the Catholic and the Orthodox Churches. But as, when Rome fell, the Catholic Church survived, and ultimately found for itself a new empire of the West, so, when Constantinople fell, the Orthodox Church continued its life, and found for itself a new empire of the East—the empire of Russia. Under Ivan the Great (1462–1505) Moscow became the metropolis of Orthodoxy; Byzantine law influenced his code; and he took for his cognizance the double-headed eagle. Ivan the Terrible, his grandson, finally assumed in 1547 the title of Tsar; and henceforth the Russian emperors became, in theory and very largely in fact, the successors of the old East Roman emperors,[1] the heads of the Orthodox Church, with the mission of vengeance on Islam for the fall of Constantinople.

[1]The Turks, occupying Constantinople, have also claimed to be the heirs of the old emperors of Constantinople; and their sultans have styled themselves *Keisar-i-Rûm*.

Subsequent Empires.—In the 19th century the word "empire" has had a large and important bearing in politics. In France it has been the apanage of the Bonapartes, and has meant a centralized system of government by an efficient Caesar, resting immediately on the people, and annihilating the powers of the people's representatives. Under Napoleon I. this conception had a Carolingian colour: under Napoleon III. there is less of Carolingianism, and more of Caesarism—more of a popular dictatorship. While in modern France empire has meant autocracy instead of representative government, in Germany it has meant a greater national unity and a federal government in the place of a confederation. The German empire (1870–1918) was at once like and unlike the old Holy Roman empire. It was unlike the old mediaeval empire; for it had no connection with the Catholic Church, and no peculiar relation to Rome. But it was like the Holy Roman empire of the 17th and 18th centuries—for it represented a federation, if a more real and more unitary federation, of the several states of Germany. The likeness is perhaps more striking than the dissimilarity; and in virtue of this likeness, and because the memory of the old German *Kaiserzeit* was a driving force in 1870, we may speak of the modern German empire as the successor of the old Holy Roman empire, if only we remember that we are speaking of that empire in its last two centuries of existence. The "empire of Austria," on the other hand, as it existed from 1804 to 1918, was not an empire in the sense of a federation, but a convenient designation for a sum of territories, ruled by a single sovereign under various titles (king of Bohemia, archduke of Austria, etc.), and very imperfectly unified in a single political system. The title of emperor was assumed in Austria, as we have seen, through an historical accident; and, though the Habsburgs of the 19th century were personally the lineal descendants of the old Holy Roman emperors, their empire was in no sense the successor or representative of the old Holy Roman empire of the middle ages.

There is one empire which remains to be mentioned—an empire which, unlike the other empires of which we have spoken, is entirely independent of the tradition and memory of Rome. Thus is the British empire (*q.v.*) or, as it is coming more and more to be called, the British commonwealth. It is an empire so much *sui generis*—a federation of national states at once so independent and so interconnected—that it is altogether a matter for separate consideration. This much, however, may be said of its nature. The British empire is, in a sense, an aspiration rather than a reality, a thought rather than a fact, a common culture and not a common government; but, just for that reason, it is like the old empire of which we have spoken; and though it be neither Roman nor Holy, yet it has, like its prototype, one law, if not the law of Rome, at any rate the common law of England—one faith, if not in matters of religion, at any rate in the field of political and social ideals.

BIBLIOGRAPHY.—*See*, in the first place, J. Bryce, *Holy Roman Empire* (1904 ed.); J. von Döllinger, "The Empire of Charles the Great" (in *Essays on Historical and Literary Subjects*, trans. by Margaret Warre, 1894); H. Fisher, *The Mediaeval Empire* (1898); E. Gibbon, *The Decline and Fall of the Roman Empire*, edited by J. B. Bury. It would be impossible to refer to all the books bearing on the article, but one may select (i.) for the period down to 476, H. Stuart Jones, *The Roman Empire* (1908), an excellent brief sketch; H. Schiller, *Geschichte der römischen Kaiserzeit* (1883–88); O. Seeck, *Geschichte des Untergangs der antiken Welt* (1897, etc.); and the two excellent articles on "Imperium" and "Princeps" in Smith's *Dictionary of Greek and Roman Antiquities* (1890); (ii.) for the period from 476 down to 888, T. Hodgkin, *Italy and her Invaders* (1880–1900); F. Gregorovius, *Geschichte der Stadt Rom im Mittelalter* (1886–94; Eng. trans. 1894–1900); E. Lavisse, *Histoire de France*, II. i. (1901); J. B. Bury, *History of the Later Roman Empire* (1889); (iii.) for the Holy Roman Empire of the German nation, W. von Giesebrecht, *Geschichte der deutschen Kaiserzeit* (1881–90); J. Ficker, *Das deutsche Kaiserreich* (1861), and *Deutsches Königtum und Kaisertum* (1862); and H. von Sybel, *Die deutsche Nation und das Kaiserreich* (1861). (E. B.)

EMPIRE COTTON GROWING CORPORATION, THE. This body grew out of the British Cotton Growing Association, founded in 1904, to develop fresh cotton fields within the British empire. It is a body representative both of the industry and the State. The income of the Empire Cotton Growing Corporation is derived in part from a capital contribution of nearly £1,000,000 made by the Government, and in part from the proceeds of a levy of 6d. per bale on all cotton purchased by British spinners. The British Cotton Growing Association retains its separate identity, and works in close alliance with the corporation; its chief work is the development of new areas, and the handling of the cotton, *i.e.*, ginning, baling and marketing, and it is particularly concerned in research work and the training and supply of experts. (*See* TROPICAL AGRICULTURE.)

From small beginnings the amount of cotton grown in new fields in the British empire (excluding India) increased to 82,000 bales in 1914, 261,900 in 1924, and 439,300 in 1926, of the approximate value of £9,301,300. The significance of these figures lies in the fact that 25 years ago West Africa exported no cotton, Uganda was just settling down after a civil war and was in the throes of sleeping sickness, and in the Sudan the first experiments were being made. In 1927 at least 140,000 bales were produced in the Sudan alone.

In 1928 several million pounds of "artificial cotton" were marketed in England at a fixed price; less than that of real cotton. This new product, successfully grown in Sussex and Essex counties, was transplanted from British Guiana. It was accidently discovered when a bird was found picking a certain plant, stripping and treating it for its nest and evolving a fibre that resembled cotton. It is said to meet every demand of the "coarse count" required by the British cotton industry and can be treated by existing cotton machinery. It is also asserted that its yarn can be blended with silk and wool and will take dyes with ease.

EMPIRE MARKETING BOARD. An official non-political body appointed in May, 1926, to advise the British secretary of State for Dominion Affairs, who is its chairman *ex officio*, in his control of an annual grant, voted by Parliament for the furtherance of the marketing in Great Britain of Empire products, including in the first place home agricultural produce. The board acts largely upon the recommendations of the Imperial Economic Committee though its work covers in some respects a wider field.

Mr. Baldwin, in explaining to Parliament (Dec. 1924), that the Imperial Economic Committee would forthwith be appointed and would be charged with the duty of advising the projected executive committee—subsequently created as the Empire Marketing Board—stated:—"In giving this assistance it is the hope and intention of the Government that it should be used to enable the Dominions to secure a larger share of that part of the home market which has to be supplied by importation from abroad. The Dominions have always recognized that our home producers have and should always have the first place in the home market but they ask—and we think rightly ask—that they should have a preference over foreign countries as regards that part of the home market which cannot be supplied by the home producer." The duty of the Empire Marketing Board to the home producer was thus made clear from the outset.

The membership of the board includes certain members of the Government *ex officio* together with representatives of the oversea parts of the Empire, of different political parties and other organizations appointed by the secretary of State. The membership of its committees includes also men of recognized experience in the widely various branches of the board's activity.

The board does not allow itself to be influenced by any consideration of party politics, and it endeavours to work through existing Government departments and other existing institutions rather than independently. There are, however, certain questions, notably publicity and marketing investigations, with which the

board has been obliged to deal directly. Its work fell naturally into two main branches, the one publicity and the other research, including both scientific research and economic investigation.

Research.—The board has made no attempt itself to engage directly in scientific research. Instead, it has regarded its proper functions as being the fortifying of existing scientific institutions in such measure as to enable them to intensify or to develop their work and the establishment of new institutions to meet new and proved needs.

In its allocation of grants it is consistently guided by the different Government organizations, at home and overseas, best qualified to advise it. Among the subjects of research work in aid of which grants have been made by the Empire Marketing Board are—tropical and sub-tropical research, including the establishment or strengthening of research stations, low temperature research, horticultural research, entomological research including the eradication of insect pests and the control of noxious weeds, animal breeding, and animal husbandry, including enquiries into the mineral contents of natural pastures.

Many of the board's grants are made conditional upon the receipt of contributions from other sources, and a considerable volume of research work has thus been put in hand at a relatively small expense to the Empire Marketing fund.

In addition to pure research work, the board has also interested itself in economic investigation, particularly in questions concerning the packing, grading and transport of certain foodstuffs. A substantial grant was placed at the disposal of the Ministry of Agriculture and Fisheries to be devoted to the interests of the home producer in this field. (S. G. T.)

EMPIRE STYLE, a term loosely describing the neo-classic style which developed in France during the consulate and empire of Napoleon, spreading rapidly throughout Europe and even to America. It originated primarily in Napoleon's desire to re-create the grandeur and luxury of imperial Rome. To this desire the spirit of the times was particularly congenial: scientific archaeology was beginning, knowledge of classic detail was increasing and the popular imagination was being fired by excavations at Pompeii and Herculaneum. In addition to the purely Roman motives, certain Egyptian ideas, such as the sphinx, were adopted, due to Napoleon's Egyptian campaign. In architecture, the style is characterized by monumental grandeur and a close following of Roman precedent, as in the front of the Chamber of Deputies, Paris. In furniture, rectangularity, massiveness and a great use of bronze *appliqué* ornament are universal. Where curves occur they are large and swelling, as in the ends of the typical sofa of the period. The use of heavy textiles, frequently embroidered with Napoleon's monogram or the symbolic bees, was widespread. The style lasted in a modified form until about 1840. The later forms are unduly monotonous and heavy. (*See* MODERN ARCHITECTURE.)

EMPIRICISM, in philosophy, the theory that all knowledge is derived from sense experience (from Gr. ἔμπειρος skilled in, from πεῖρα, experiment). It is opposed to all forms of intuitionalism, and holds that the mind is originally an absolute blank (*tabula rasa*), on which, as it were, sense-given impressions are mechanically recorded, without any action on the part of the mind. The process by which the mind is thus stored consists of an infinity of individual impressions. The frequent or invariable recurrence of similar series of events gives birth in the mind to what are wrongly called "laws"; in fact, these "laws" are merely statements of experience gathered together by association, and have no other kind of validity. In other words from the empirical standpoint the statement of such a "law" does not contain the word "must"; it merely asserts that such and such series have been invariably observed. In this theory there can strictly be no "causation"; one thing is observed to succeed another, but observations cannot assert that it is "caused" by that thing; it is *post hoc,* but not *propter hoc.* The idea of *necessary* connection is a purely mental idea, an a priori conception, in which observation of empirical data takes no part; empiricism in ethics likewise does away with the idea of the absolute authority of the moral law as conceived by the intuitionalists. The moral law is merely a collection of rules of conduct based on an infinite number of special cases in which the convenience of society or its rulers has subordinated the inclination of individuals. The fundamental objection to empiricism is that it fails to give an accurate explanation of experience; individual impressions as such are momentary, and their connection into a body of coherent knowledge presupposes mental action distinct from mere receptivity. Empiricism was characteristic of all early speculation in Greece. During the middle ages the empiric spirit was in abeyance, but it revived from the time of Francis Bacon and was systematized especially in the English philosophers Locke, Hume, the two Mills, Bentham and the associationist school generally. (*See* ASSOCIATION OF IDEAS; METAPHYSICS; PSYCHOLOGY; LOGIC; besides the biographies of the empirical philosophers.)

In *medicine,* the term is applied to a school of physicians who, in the time of Celsus and Galen, advocated accurate observation of the phenomena of health and disease in the belief that only by the collection of a vast mass of instances would a true science of medicine be attained. This point of view was carried to extremes by those who discarded all real study, and based their treatment on rules of thumb. Hence the modern sense of empirical as applied to the guess work of an untrained quack or charlatan.

EMPLOYEE REPRESENTATION, a term used (especially in the United States) to designate a plan whereby management seeks to establish a point of contact with its employees on matters of mutual interest to secure greater co-operation, mutual confidence and good-will. The first attempts to bring this about in the U.S.A. took the form of shop committees, whose principal function was to provide a means for bringing the wants or grievances of employees to the attention of the management. The second stage of development was due to the activities of the National War Labor Board, the U.S. Railroad Administration and the Shipbuilding Labor Adjustment Board, which agencies used the shop committee as part of the machinery for adjusting labour disputes. Since that time, employee representation plans have been the subject of much controversy. Labour leaders have claimed that the movement is an attempt to disrupt labour unions. In other instances, labour unions have co-operated with the management in the establishment of shop councils.

Employee representation plans may be roughly classified into: (1) those having very limited power, usually advisory only; (2) those which have definite provision for settling disputes, and where the representatives take some actual part in settling the point at issue; (3) those which either directly or indirectly give the employees representation on the board of directors of the company; and (4) those which maintain some direct affiliation with labour unions. Another way to classify employee representation plans would be to separate them into those which maintain some direct connection with a trade union or are non-conflicting, and those which have been organized as a substitute for a union organization, either because the employer wished it so or because no union existed. The structure of the plans is either a joint committee type of organization wherein representatives of the employee and the management meet in committee or it is imitative of the so-called Federal form of Government. This latter type usually provides for such bodies as a house of representatives made up of employee representatives, a senate made up of supervisory employees, and a cabinet made up of executive officers. The details of arbitration machinery, powers and procedure vary widely. In common with nearly all of the so-called industrial relations activities, the success of employee representation rests upon the motives underlying the inauguration and continuance of the particular plan in question. Properly carried out, it provides an opportunity for managers to learn much about men and these to learn much about management. (O. G. S.)

EMPLOYEE STOCK OWNERSHIP, a plan whereby employees are offered an opportunity to purchase the stock of the company which employs them. Plans of this kind are usually undertaken by a company in the belief that they will promote a more intimate relationship with employees, encourage thrift, attract a better type of employee and possibly reduce turnover. From the standpoint of the employee, there are both advantages

and disadvantages in such stock ownership plans. While they provide an opportunity for regular savings and perhaps profitable investment of funds, they tend to multiply his economic risks in that his job and his invested savings are both dependent on the success of the same enterprise. The stock sold to employees may be either "common" or "preferred," the desirability of either depending largely upon the financial structure of the company involved. Whether or not the company wishes its employees to hold stock carrying a voting privilege, also becomes a consideration in the choice of stock to be sold. The stock itself is usually secured by treasury issue or by the setting aside of a block of new issue for sale to employees. Occasionally, a special employees' stock is issued by the company. While the actual sale of stock is usually made directly by the company to its employees, there are instances where the company allows the sale to be carried on through an employees' organization. Eligibility requirements for participation in employee stock ownership plans vary widely. Some companies allow all employees to subscribe; others require a minimum term of employment before eligibility; others limit the subscription to certain classes of employees, such as those holding responsible positions or perhaps senior executives only. Salary may also be a determining factor in eligibility. The number of shares which an employee may purchase is almost always controlled. These restrictions are most commonly related to salary. Length of service may also be considered.

Instead of selling stock to employees at the prevailing market price, many employers offer the stock at a price slightly below its market value, in order partially to protect the employee against price fluctuation, and also to make the offer additionally attractive. Some companies offer to assist the employee in the purchase of the stock and have a definite scale of contribution often based on length of service and number of shares. Again, other companies give stock to their employees either as a reward for meritorious service during a given period of time or as a reward for length of service; thus the stock distribution is actually a bonus plan where stock is given in lieu of cash. Where the employee pays for all or part of the stock, this may be accomplished either by cash payment in full at the time of purchase, by monthly installments over a given period, by payment into a convertible fund or by subscription to a stock pool. Method of payment is usually liberal and where deferred payments are allowable, arrangement is often made for payroll deduction. Title to the stock, however, ordinarily does not pass until the payments have been completed, nor are dividends credited to the employee except as payments on account. The sale or transfer of stock is usually restricted. Many companies offer inducements to employees to hold stock. These inducements most frequently take the form of extra dividends. Where the sale of stock is restricted, a re-purchase provision is included in the plan. The success of employee stock ownership plans depends primarily upon the liberality and soundness of the plan, the existence of mutual confidence between the employer and the employee, and the business integrity of the organization as a whole. (O. G. S.)

EMPLOYEES, TRAINING OF. Arrangements for the training of employees date back as far as industrial history. They were among the most important objects of the mediaeval guilds (*q.v.*) and the whole basis of the system of apprenticeship (*q.v.*). But with the introduction of the factory system the personal relationship between the master craftsman and the beginner changed substantially, and since then employee training has been carried on, if at all, generally in an unorganized, sporadic, haphazard and ineffective way.

Corporation Schools.—In the United States, however, as early as the '90s, a few corporations had formed what were commonly called "corporation schools," the assumption being that the training function should be exercised by a department especially equipped and trained to perform the job of training the employees. This change was due to the assumption that the foreman could not be expected to train employees partly because he was poorly equipped to teach and could not be trained to teach and partly because it was assumed that he had too many other responsibilities. It was not unusual for corporations establishing schools or educational departments to appoint as the head of that department some one who, presumably, was better able than the supervisor to train employees. Not infrequently an engineer or a public school teacher or official was chosen for such a position, partly on the basis of a more complete education and often partly on the basis of personality. By 1913 there were in America a sufficient number of corporation schools to warrant the formation of a National Association of Corporation Schools, and this association grew in influence and numbers substantially from 1913 until 1921. Meanwhile, similar associations were formed in England, France, Japan and in some other countries. Most of these schools adopted the pedagogical methods which had been in vogue in the public schools and in engineering and other colleges during the days when the director of education had attended them. Without any particular knowledge of pedagogical methods, he naturally adopted the methods with which he was most familiar including often the formalism of the classroom and its more or less inevitable removal from occupational activity or other relationships. By 1918 or 1919 many corporations in America were training employees without the formality of a corporation school and this trend of thought found its expression in the renaming of the association, National Association of Corporation Training.

There has been a strong tendency for corporations to abandon the formal classroom instruction method of training and to return to the earlier method of making training fundamentally the responsibility of the line supervisor. There is, however, this very important difference, namely, it is being recognized that the supervisor should be trained in the teaching process and that he can be trained. Furthermore, it is being recognized that the instructional materials for training purposes, usually referred to as instructural outlines, must be organized in such a way that the supervisor will cover all aspects of the training programme so that they will not be left to mere chance.

Industrial School Training Inadequate.—During this change in methods of training employees, United States public educational authorities were giving more and more attention to the preparation of youth for industrial and commercial pursuits. The industrial and trade school supported by communities as part of the public educational system became quite general. The first tendency in this movement was to assume that the public schools could take over a very large part of the programme of training for industry as well as education for life, and for a time it was easy to find vigorous advocates of public educational institutions which would entirely relieve industry and commerce of the problem of training for the job. There has been, however, a distinct swing away from the assumption that the public schools could entirely relieve industry of its own responsibility. It is now realized that the public schools have failed to perform the whole task of education and training for occupational activity, that the failure was inevitable, that the problem cannot be transferred in its entirety to the public schools and that industry, whether it wishes to or not, must assume its own share of responsibility for training.

At first many corporation schools undertook what is generally conceded to be the responsibility of the public schools, *i.e.*, the responsibility of educating young people and even others for the broader relationships of life, most of which, of course, have some bearing on the effectiveness of an employee in his occupation. For the most part, this tendency has been or is being abandoned. Organized business now expects the public schools to prepare youth for most life relationships, and by eliminating this feature from its own programme, industry can devote itself more intensively and effectively to training for the job.

Training a Management Problem.—A very large number of companies have what is commonly referred to as an educational department or an educational director. One of the largest electric manufacturing companies has practically done away with all formal classroom instruction of employees and is concentrating its efforts in teaching the foreman to train. A syllabus for supervisors in an electrical public utility company consists largely—practically 90 to 95%—of material which deals with teacher training for foremen, the assumption being that in order to make the training programme really effective, steps must be taken to make

the training of the worker continuous from the time of entering the business until he leaves it, and on the principle that the best training is that which is given in connection with actual work under normal circumstances of supervision, incentive and responsibility. The president of a large company in the United States has stated that management is in large measure, 80 to 90%, an educational and training job. He illustrates by saying that on one occasion a number of executives of this company analysed exactly what management is in terms of specific operations and, that after classifying all of the typical operations, nine out of ten of them were listed under education and training.

The preparation of instructional materials is, of course, one of the most important steps in a training programme. At one time, the usual practice was for the instructor himself to learn every element of the job and then proceed to convey the information to the employee usually by the lecture process in a classroom. More recently emphasis is being laid on the job difficulties of the employee, and the result has been a pronounced movement in the direction of analysing the job difficulties and the man requirements, the learning difficulties of the employee and the order in which these appear. Out of this analysis it is possible to set up a body of instructional materials which attack, not training for the whole job, but rather, the problem of training the employee to overcome the job difficulties. Another important step in a modern training programme is an analysis of the teaching process in terms of the difficulties of the foreman or department head in training his employees for the job. Such an analysis leads to the development of a body of instructional materials on the technique of training and is naturally followed by a programme of instructing the supervisor to train. Employee training has come to be recognized as a management problem and the subject of training employees takes a very large place in all discussions of management societies the world over. (W. J. Do.)

EMPLOYERS' ASSOCIATIONS: *see* ASSOCIATIONS, INDUSTRIAL.

EMPLOYERS' LIABILITY: *see* WORKMEN'S COMPENSATION.

EMPLOYMENT EXCHANGE, an agency for bringing together employers requiring labour and workpeople desiring work; also variously known as a Labour Exchange, Labour Bureau or Employment Agency. The primary function is to record "vacancies," *i.e.*, requirements of an employer, with conditions offered by him, and to register qualifications of applicants for employment, with a view to submitting suitable workpeople for the vacancies. Such an agency may be privately owned, or under municipal or State control or management, may charge fees to employers or workpeople, or both, for the introductions effected, or may defray the expenses of administration from private or public funds. Its scope may be limited as to the trades and occupations in which notifications of vacancies are received, or as to the classes of workers (skilled, unskilled, male or female) placed in employment. An exchange may be local, national or, exceptionally, international in its range of action. Finally, the notification of vacancies may be obligatory upon employers, while refusal of suitable employment offered may entail suspension or disallowance of an applicant's out-of-work pay. (*See* UNEMPLOYMENT INSURANCE.)

Although the functions of employment exchanges (particularly in the case of privately owned "registry offices" for domestic servants) may terminate with the "vacancy work" or "placing," other duties are usually combined with this work, especially when the exchanges are under the direction of a public authority. A combination of vacancy work with the administration of out-of-work pay schemes has long been the practice of Trades Unions and is an essential feature of the National Unemployment Insurance scheme of Great Britain. The association of exchanges with the payment of unemployment benefit enables, in Sir Wm. Beveridge's words, "the beneficial and natural test" of a situation offered through the exchange to be substituted for abstract enquiries directed to ascertaining the genuineness of an applicant's search for work. "The two systems are complementary; they are man and wife; they mutually support and sustain each other" (Mr. Winston Churchill, House of Commons, May 19, 1909).

Theory of Employment Exchanges.—The object of exchanges is to increase the mobility of labour, but at the same time to prevent its needless displacement. By concentrating the notification of vacancies and the registration of applicants for employment at convenient centres linked together by a clearing house system, the numbers, classes, occupations, and the duration of the employment of the industrial population, together with the opportunities for further employment, are recorded and tabulated. The fluctuating requirements of the labour market, themselves a cause of unemployment, are thus measured; and supply is related to demand. If the surplus is local, by the use of a clearing house system which informs the local exchange of opportunities of employment elsewhere (aided by the advance of railway fares given unconditionally or by way of a loan), the surplus is enabled to transfer to areas of shortage and to find work there. If the surplus is general, as in outdoor occupations of the building trade in winter, the dovetailing of occupations, by the transfer of the seasonably unemployed to subsidiary occupations or to any alternative work for which they may be qualified, is assisted by the use of the same machinery. Where the surplus is both general in extent and permanent in character (as may happen when new industrial processes or changes in fashion modify existing methods of production) the exchanges, guide displaced workers to other forms of employment. Finally, the exchange may serve as a medium for paying unemployment benefit.

The practical application of the theory of employment exchanges would present no difficulties if every unemployed person were free to take any kind of work wherever it was available. The mobility of labour, the interchangeability of occupations, the existence of subsidiary qualifications, the ability of unemployed men to move their homes, all of which are implicit in the theory, are, however, necessarily affected by differences in wage levels, increasing trade specialization, difficulties of occupational transfers, housing shortages, family circumstances, and a variety of psychological factors. It may be doubted, too, whether prejudices due to experiences of the exchange system in its early stages of development have yet disappeared. A loss of time and a slowing down of production are anticipated by some critics if, instead of engaging labour at the works gates, *all* vacancies are notified to the labour exchange and the employer waits while machinery outside his control selects for his approval and engagement apparently suitable men. Against this it is contended that industry as a whole saves time by the use of an agency which concentrates reserves of labour, assesses its industrial value, and directs to each establishment, as required, suitable men. The view expressed is that the best workmen do not register at exchanges and therefore are not available for submission. If, however, the exchanges are associated with the payment of unemployment benefit, all claimants are automatically within the field of selection. A more serious objection has been made by trade unionist critics that the exchanges may be used to fill vacancies caused by trade disputes; also that, as no preference is shown to trade unionists in submitting applicants for vacancies, the organization of labour to which they aspire may be hindered. These objections were taken into account when labour exchanges were established in Great Britain and the act of 1909 provided that no submissions should be made to "black-leg" vacancies without the applicants' consent and that men refusing to be so submitted or otherwise to accept employment below standard conditions should suffer no disability.

Employment Exchanges in Great Britain.—Under powers conferred upon local authorities in Great Britain by the Unemployed Workmen act of 1905, exchanges had been established in London and some provincial centres, while a co-ordinating author-

ity for the metropolis, the Central (Unemployed) Body, had maintained, with some success, employment exchanges, including a clearing house system. Prior to this certain metropolitan borough councils and provincial local authorities had set up labour bureaux, which, however, worked independently of each other and had a limited range. Both bureaux and exchanges, however, were so generally associated with relief works that they mostly failed to secure the confidence of employers and the best type of work-people. From 1905–09 the treatment of distress due to unemployment came under the review of the Royal Commission on the Poor Laws. While criticizing the existing exchanges, both for their organization and limited scope, the commission were satisfied that their failure had been due to local and special causes and not to any inherent defect. The commission accordingly recommended that:—

"1. A national system of labour exchanges should be established and worked by the Board of Trade for the general purposes of assisting the mobility of labour and of collecting accurate information as to unemployment.

"2. The labour exchanges should be in charge of officers of the Board of Trade, assisted by committees of employers, workmen, and representatives of local authorities.

"3. There should be no compulsion to use the labour exchanges, but the object of the Government and the local authorities should be to encourage and popularize them in every way, *e.g.*, by propaganda and by making use of the exchanges in engaging workmen.

"4. The labour exchanges should be granted free postal and telephone facilities by the State.

"5. Arrangements should be made to enable the labour exchanges to grant passes entitling workmen travelling to a situation to specially cheap railway fares; in suitable cases the cost of the passes might be provided and recovered afterwards from the workmen."

The Labour Exchanges act of 1909 embodied most of the commission's recommendations. A national system of exchanges, charging no fee to employers or workpeople making use of it, was established by the Board of Trade, and by Feb. 1910, 61 offices, including 19 taken over from the Central (Unemployed) Body, were available to the public. The introduction two years later of the State Unemployment Insurance scheme, its great extension, and the growth of unemployment after the World War led to considerable increases in the number of exchanges. At the end of 1927 there were nearly 400 exchanges and 700 branch employment offices maintained by the Ministry of Labour, to whom the functions of the Board of Trade in this matter had been transferred in 1917. The previous year had seen the term "employment exchanges" officially substituted for the statutory designation.

Statutory exchanges and branch employment offices are administered by the Employment and Insurance department of the ministry of Labour, consisting of a headquarters staff in London and seven divisional offices under the charge of a divisional controller. Ordinarily, all exchanges have separate departments for men and women. Where the local education authority does not establish juvenile employment bureaux under the Choice of Employment Act, 1910 (embodied in Section 107 of the Education Act, 1921), the exchange has a branch for assisting juveniles to find suitable employment. It has not always been practicable to house all departments in the same building but, wherever possible, this is done. At each divisional office there is a senior woman officer responsible for the women's and juveniles' section. Exchanges are assisted by advisory committees consisting of equal numbers of employers' and workpeople's representatives and a certain number of individuals nominated by local authorities, ex-service men's associations, juvenile advisory committees, territorial force associations and bodies interested in social work.

Vacancy Work.—It has already been shown that, through the association in Great Britain of unemployment insurance administration with exchange work, all unemployed persons claiming benefit are registered at one or other of the 1,100 local offices of the Labour Ministry. All such persons attend at the nearest office to sign the unemployed register as often as may be required. This attendance from day to day of unemployed workpeople of all occupations serves also to provide a "live register" of the facts of unemployment and to relate the supply of labour to the demand. If a new factory is to be erected in a semi-rural district where there has hitherto been no industrial development, the contractors, who may be strangers to the district, will notify their requirements to the nearest exchange. There will be vacancies for navvies, bricklayers, masons, carpenters, fitters, skilled and unskilled workers. Probably a sufficient number of labourers will be signing the local unemployed register to meet the employer's requirements for this part of the "order." If so, the exchange manager will give each suitable man an introduction card to the works foreman; the foreman fills in the card and returns it to the exchange to show whether the applicant has been engaged or not. Where the area of selection of men has to be widened, the exchange manager will telephone one or more adjacent exchanges to ascertain whether any suitable applicants are within daily travelling distance of the work, and similar arrangements for interview are made. If, owing to local shortages of some of the types of labour in demand, a still wider circulation is necessary, this is obtained by communication with the divisional clearing house. The latter receives at frequent intervals from each exchange in its area "surplus labour slips," showing for each of the occupations in demand in its own or another clearing house area the numbers and special qualifications of applicants on the local register who are available for submission to distant vacancies. The clearing house may therefore be in a position to refer the "vacancy exchange" (the office to which the "order" has been given) to an "applicant exchange" (*i.e.*, an office at which suitable men of the occupations in demand are signing the unemployed register) and thus arrange for the submission to the employer of particulars of suitably qualified men. Where the divisional clearing house has no positive knowledge of the whereabouts of surplus labour of the required kind, it includes particulars of the "order" in the daily list of vacancies circulated to all exchanges in the area, or, if necessary, to the London headquarters for inclusion in the printed *National Clearing House Gazette* which is distributed daily to all exchanges in the country. Divisional and national clearing house lists are also exhibited in the "vacancy section" of all exchanges. Railway warrants are issued in necessary cases to enable the men engaged to travel to their new employment, or, in some cases, to be interviewed prior to engagement. Sometimes the fare is paid by the employer, sometimes the amount is deducted later from the wages by weekly instalments; the vacancy exchange normally acts as the collecting office for the sums advanced. Thus, though the use of the national clearing house enables the whole labour supply of the country to be drawn upon where necessary, the local and nearer sources are exhausted first.

Exchange officers are required to act impartially in submitting applicants to vacancies, having regard only to industrial suitability, save that, as a matter of Government policy, a preference is given to ex-service men as between equally qualified applicants. In appropriate cases the branch secretary of the trade union concerned is consulted to see whether any unemployed members of his branch are suitable and available for the vacancy.

Statistics.—Although the Labour Exchanges act imposed no obligation on employers to notify vacancies to the exchanges, many important industrial undertakings recruit their labour entirely through their agency. In Aug. 1927 the Mining Association of Great Britain agreed, under s. 18 of the Mining Industry Act, 1926, to restrict until the end of 1929 the engagement of new entrants into the coal-mining industry. All vacancies for adults in practically all forms of colliery employment are therefore notified to the exchanges in order that, within a period of 14 days, men formerly employed in the specified occupations can be submitted for engagement. If none can be found to take the employment offered within this period, a new entrant may be engaged. On a register of approximately 1,000,000 unemployed persons, the exchanges in 1926–27 placed in employment some 25,000 to 30,000 applicants each week. In 1927–28 the average weekly un-

employed register was 1½ millions and again the exchanges placed in employment each week some 25,000 to 30,000 applicants.

Employment Exchanges in Other Countries.—Since the beginning of this century exchanges resembling in their main features those established in Great Britain have been operating in several European countries. The municipal and State systems of Germany served as a model for the British exchanges. The adoption internationally of a uniform system has resulted from the proceedings of the First (Washington) Session of the International Labour Conference, 1919, which had been brought into existence by the Treaty of Versailles (Part XIII.). A draft convention on employment adopted by the conference provided in its second article as follows:—

"Each member (*i.e.*, State) which ratifies this Convention shall establish a system of free public employment agencies under the control of a central authority. Committees, which shall include representatives of employers and workers, shall be appointed to advise on matters concerning the carrying on of these agencies.

"Where both public and private free employment agencies exist, steps shall be taken to co-ordinate the operation of such agencies on a national scale.

"The operations of the various national systems shall be co-ordinated by the International Labour Office in agreement with the countries concerned."

In addition to Great Britain the under-mentioned members of the International Labour Organization have ratified (1928) the Employment Convention and, where their legislation was not previously in accord, have since taken steps, or are adapting their legislation, to give effect to it, viz., Austria, Bulgaria, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, India, Irish Free State, Italy, Japan, Luxemburg, Norway, Poland, Rumania, Serb-Croat-Slovene Kingdom, South Africa, Spain, Sweden and Switzerland.

Certain States which are not members of the International Labour Organization or have not ratified the convention have within their territories employment exchanges under Government control and satisfying some or all of the conditions laid down by the conference. The New Zealand Government, for example, established exchanges so long ago as 1891.

United States.—In the United States public employment offices have been organized by municipalities, States and by the Federal Government. New York city established the first municipal office in 1834. Los Angeles and Seattle established municipal offices during the panic of 1893. From that time on, the demand for seasonal labour in the farming countries caused employment offices to be opened in many western cities. In 1907 and in 1913, the movement expanded again and over 40 municipal employment offices were opened. Many of these subsided as their period of usefulness ended, or they were absorbed by other agencies. The first State employment agency was established in Ohio in 1890. In 1927, 33 States were operating public employment offices. The Federal Government established an employment agency in 1907 fo the placement of immigrants. This was known as the division of information of the bureau of immigration. In Jan. 1918, the U.S. employment service was organized. State agencies were considered as local units and many of the then existing local offices were absorbed. This rather extensive movement did not last long and in 1919 the so-called field service work of the Government was discontinued and the individual States reorganized their local employment agencies on an independent basis.

In the absence of an extensive system of public employment agencies, there has been a marked development of the so-called private or semi-public employment agency. These have been variously financed by employers, employees, fraternal associations, professional organizations, schools, etc. Employment agencies organized by employers are often administered by chambers of commerce, trade associations or merchants' associations. They usually flourish when labour is scarce. Agencies organized by workers are usually administered through trade unions for the purpose of keeping their members employed. Many fraternal organizations, professional bodies, colleges and training schools maintain employment agencies for the purpose of securing positions for their members or their graduates. They are, therefore, more apt to be concerned with supplying technical and professional help. Philanthropic organizations have in many instances established agencies to provide relief during periods of widespread unemployment. In addition to the foregoing, and important because of the extensive nature of its operations, is the employment agency organized as a business enterprise and on a fee-charging basis. Many of these organizations do a flourishing business, have a large staff of trained employees and a wide range of contact. Some States now seek to regulate this type of agency by requiring licences and bonds. The need for regulation, however, is the exception rather than the rule. The larger private employment agencies are usually sound and reputable institutions. Many conduct extensive studies and issue reports on the labour market, current rates of pay and similar data.

The larger employers of labour in the United States do not depend entirely on outside employment agencies, either public or private, for the continuance of their labour supply. Most large business organizations maintain extensive employment or personnel departments. Contacts are developed with schools and professional associations so that suitable applicants for the positions requiring special training may be secured. These departments also study intensively the problems of labour turnover, wages rates and sources of labour supply and all the related problems affecting the maintenance of an adequate operating personnel. (O. G. S.)

EMPOLI, town, Tuscany, Italy, province of Florence, 20 m. W. by S. of Florence by rail. Pop. (1921) 8,120 (town); 21,730 (commune). It is 89 ft. above sea-level, to the south of the Arno. The principal church, the Collegiata, or Pieve di S. Andrea, founded in 1093, still preserves the lower part of the original arcaded façade in black, white and coloured marble. The principal square is surrounded by old houses with arcades. Empoli is on the main railway line from Florence to Pisa, and is the point of divergence of a line to Siena.

EMPORIA, a city of eastern Kansas, U.S.A., on the Neosho river, 70m. S.W. of Topeka; the county seat of Lyon county. It is on Federal highway 50S, and is served by the Missouri–Kansas–Texas and the Santa Fe railways. The population at the State census of 1925 was 12,243 (90% native white). The city has railroad shops and other manufacturing industries, with an aggregate output valued in 1925 at $1,211,425; but it is primarily an educational centre and a commercial metropolis for a large agricultural and stock-raising region. The original State normal school of Kansas, established at Emporia in 1863, became the Kansas State teachers' college of Emporia in 1923, and now has an enrolment of over 5,000. The College of Emporia (enrolment about 500) is a Presbyterian co-educational institution, established in 1882. Emporia was settled in 1856 and incorporated as a city in 1870. It is the home of William Allen White (b. 1868, in Emporia), who in 1894 bought the Emporia *Gazette* (established 1890) and became its editor.

EMPORIUM, a trade-centre such as a commercial city, to which buyers and dealers resort for transaction of business. (From Gr. ἐμπόριον; ἐν, in, and stem of πορεύεσθαι, to travel for purpose of trade.) The word is often applied to a large shop.

EMPSON, SIR RICHARD (d. 1510), English statesman, born at Towcester, was in 1491 one of the members of parliament for Northamptonshire and speaker of the House of Commons. Early in the reign of Henry VII. he became associated with Edmund Dudley (*q.v.*) in carrying out the king's rigorous and arbitrary system of taxation. He was made a knight in 1504,

and was soon high steward of the University of Cambridge, and chancellor of the duchy of Lancaster; but his official career ended with Henry's death in April 1509. Thrown into prison by order of the new king, Henry VIII., he was charged, like Dudley, with the crime of constructive treason, and was convicted at Northampton in Oct. 1509. His attainder by the parliament followed, and he was beheaded on Aug. 17 or 18, 1510.

See Francis Bacon, *History of Henry VII.*, ed. J. R. Lumby (Cambridge, 1881); and J. S. Brewer, *The Reign of Henry VIII.*, ed. J. Gairdner (1884).

EMPYEMA, a term in medicine applied to an accumulation of purulent fluid within the cavity of the pleura (*see* HEART AND LUNG, SURGERY OF).

EMPYREAN, the place in the highest heaven, which in ancient cosmologies was supposed to be occupied by the element of fire. It was used as a name for the firmament, and in Christian literature (so Milton, in *Paradise Lost*) for the dwelling-place of God and the blessed, and as the source of light. The word is used both as a substantive and as an adjective; it is accented on the third syllable.

EMS, a town and watering-place of Germany, in the Prussian province of Hesse-Nassau, situated on the Lahn, 11 m. E. from Coblenz on the railway to Cassel and Berlin. Pop. (1925) 7,121. There is some mining industry (silver and lead). Ems is a watering-place, its waters—hot alkaline springs—being used both for drinking and bathing. A funicular railway runs up to the Malberg (1,000 ft.), where is a sanatorium and whence extensive views are obtained over the Rhine valley. In 1786 Ems was the scene of the conference of the delegates of the four German archbishops, known as the congress of Ems, which issued (Aug. 25) in the famous joint pronouncement, known as the Punctuation of Ems, against the interference of the papacy in the affairs of the Catholic Church in Germany (*see* FEBRONIANISM).

EMS, a river of Germany, rising on the south slope of the Teutoburger Wald, at an altitude of 358 ft., and flowing generally north-west and north through Westphalia and Hanover to the east side of the Dollart, immediately south of Emden. After passing through the Dollart the navigable stream bifurcates, the eastern Ems going to the east, and the western Ems to the west, of the island of Borkum to the North sea. Length, 200 miles.

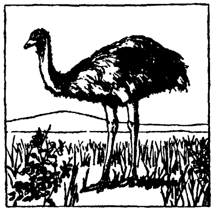
Between 1892 and 1899 the river was canalized for a distance of 43 miles. At the same time, and as part of the plan to provide an entirely German outlet for the Westphalian industrial district, the Dortmund-Ems canal was constructed. It runs from Dortmund to Meppen (94 m.) where it joins the canalized Ems (55 m.) and then follows the open river to Emden. Altogether, the canal is 170 m. in length, has a surface width of 99 ft. and a depth of 11 to 12 ft. The total fall is 230 ft., overcome by 19 locks and a ship-lift. It will take boats of 750 and even 800 tons. From Henrichenburg a branch runs to Herne, which is connected with the Rhine near Ruhrost by the Rhine-Herne canal. There is a difference in level of 46 ft. between the main canal and the Herne branch, and this necessitated a huge lift at Henrichenburg. The canal is connected with the Mittelland canal system at Bevergern. Northward traffic is mostly in coke and coal from the Westphalian coalfield, to which it brings imported iron ore and other raw material and foodstuffs.

Lindley, *Report on the Waterways of France, Germany*, etc. (Stationery Office, 1909); A. Krziza, *Emden und der Dortmund-Ems-Kanal* (Kiel, 1912).

EMSER, JEROME or **HIERONYMUS** (1477–1527), antagonist of Luther, was born of a good family at Ulm on March 20, 1477. He studied Greek at Tübingen and jurisprudence at Basel, and after acting for three years as chaplain and secretary to Raymond Peraudi, cardinal of Gurk, lectured on classics at Erfurt (1504), where Luther may have been among his audience. In the same year he became secretary to Duke George of Albertine Saxony. At first Emser sided with the reformers, but like his patron he desired a practical reformation of the clergy without any doctrinal breach with the past or the church; and his liberal sympathies were mainly humanistic. As late as 1519 Luther referred to him as "Emser noster," but the disputation at Leipzig in that year completed the breach between them. Emser warned his Bohemian friends against Luther, and Luther retorted with an attack on Emser which outdid in scurrility all his polemical writings. In the violent controversy that followed Emser wrote some eight tracts. At Duke George's instance he prepared, in 1523, a German translation of Henry VIII.'s "Assertio Septem Sacramentorum contra Lutherum," and criticized Luther's "New Testament." He also entered into a controversy with Zwingli, he took an active part in organizing a reformed Roman Catholic Church in Germany, and in 1527 published a German version of the New Testament as a counter-blast to Luther's. He died on Nov. 8, in that year.

All histories of the Reformation in Germany contain notices of Emser; *see* especially Friedensburg, *Beiträge zum Briefwechsel der katholischen Gelehrten Deutschlands im Reformationszeitalter.*

EMU or **EMEU,** the name given to Ratite birds of the family *Dromaeidae.* With the cassowaries (*q.v.*), the emus form the order Casuariiformes, peculiar to the Australian region and characterized by the fact that the "after-shaft" of each feather is as long as the main shaft (*see* RATITAE; FEATHER). The emus differ from the cassowaries in having feathers on the head, no helmet or cervical caruncles, and in bearing on their inner toes a peculiar claw. The best known species is *Dromaeus novae-hollandiae* of S.E. Australia. Next to the ostrich the largest of living birds, the emu has been much diminished in numbers by constant persecution. It inhabits open country, feeding on fruits, roots and herbage and keeping in small companies. The nest is a shallow pit in the ground containing 9 to 13 blue-green eggs, which are incubated by the cock. The young at birth are clad in striped down. The peculiar structure of the trachea is correlated with the loud booming note of the bird during the breeding season. This, or an allied species, formerly inhabited Tasmania.



BY COURTESY OF THE NEW YORK ZOOLOGICAL SOCIETY

AUSTRALIAN EMU, NEXT TO THE OSTRICH THE LARGEST OF LIVING BIRDS

EMULSIONS are mechanical mixtures of liquids that are immiscible under ordinary conditions, and which may be separated into layers on standing, heating, freezing, by agitation, the addition of other chemicals, etc. Familiar examples of emulsions are milk and butter—the first, an emulsion of oil in water; the latter an emulsion of water in oil. The term emulsion is also applied (although not with complete accuracy) to mechanical mixtures in which finely-divided solid particles are suspended in liquids in which they are insoluble. More properly, such mixtures are known as colloidal solutions or suspensoids. In dyeing, tanning, tinting of certain coloured glassware, water purification, etc., emulsions play an important part.

Froth flotation, by means of which many millions of tons of minerals annually are separated from their ores, employs emulsions of various vegetable and mineral oils (*see* METALLURGY). Basically, photography (*q.v.*) is also dependent on the use of emulsions, for dry plates and films are generally coated with gelatin emulsions.

ENAMEL, a vitreous glaze or combination of vitreous glazes fused on a metallic surface. The general term *enamels* is conveniently applied to objects of which the principal decoration consists of this material. The art is of great antiquity and probably of Western Asian origin.

I. EUROPEAN ENAMELS

It was upon pottery and brick that the ancient Egyptians and Assyrians achieved their greatest work in enamelling. As yet no

MEDIAEVAL AND MODERN PAINTED ENAMELS

1. Portrait in enamel by Léonard Limosin of Catherine of Lorraine, duchesse de Montpensier, daughter of Francis of Lorraine, duc de Guise, in the "Fine Style" of Limoges of the 16th century. She is represented wearing an amber coloured cap set with pearls and emeralds. Her costume is richly jewelled. One of the puffs on her left shoulder is pricked with the artist's name
2. Enamelled plaque of the crucifixion by Jean Limosin, descendant of Léonard Limosin, in the "Minute Style" of Limoges of the early 17th century, at the beginning of the period of decline. Three holy women mourn at the foot of the cross, and the dark blue sky is covered with clouds through which shines a golden light. The sun and moon appear on either side of the crucifix, and in the background is the city of Jerusalem
3. Painted enamel of Limoges, Pilate Washing his Hands, in the "Fine Style" of the 16th century, a style less sumptuous in colour than the one preceding it and distinctly under the influence of the Italian Renaissance
4. Triptych of painted enamel, attributed to Nardon Pénicaud, in the "Early Style" of Limoges, 15th century, representing the entombment, between the descent from the cross on the left and the resurrection on the right. The plaque is executed in bright translucent colours on a white ground, the effect heightened by picking out lights and lesser details with gold, and by using small discs of foil placed beneath the enamel on the garments to simulate gems
5. A painted enamelled plaque called "The Virgin and the Doves," executed in translucent enamels, by Alexander Fisher, a distinguished modern English enameller. Fisher does not belong to any school; his work is marked by a preference for opalescent hues

MODERN ENAMELS

1. Enamel portrait of H. Benedict de Saussure (1740–99), by Abraham Constantin (1785–1855), a Swiss, from the original by Jean Pierre St. Ours (1752–1809), also Swiss
2. Bookcover in *champlevé* enamel, made for the guestbook of the Architectural League of New York. The inserted medallions are in silver. The back has five plates in enamel, with the symbols of the arts
3. Portrait in enamel, with silver frame and base, by Alexander Fisher (1864–), reviver of the art of enameling in England. Fisher is particularly successful in combining enamel with precious metals and jewels
4. The Dream of Brahm, an allegorical subject, by Alexander Fisher
5. A group in enamel, decoration on a casket, by Alexander Fisher, combining decorative work in precious metals with enamel
6. Enamel portrait by Alexander Fisher
7. Children with bear, *cloisonné* enamel panel for a casket, by Harold Stabler, England, a contemporary worker in metals and enamels, distinguished for his decorative style and his use of strong colour
8. War Memorial, *champlevé* enamel panel, by Oswald Reeves
9. Children with leopards, *cloisonné* enamel panel for a casket, by Harold Stabler, a companion piece to the panel of 7

work of such magnificence as the great enamelled walls of the palace of Rameses III. at Tell el-Yehudia in the Delta of the Nile, or the palace of Nimrod in Babylon, has been discovered upon metal of any kind. But there were gold ornaments and jewellery enamelled of noble design in opaque turquoise, cobalt, emerald green and purple, some of which can be seen at the British Museum and the Louvre.

Many exquisite pieces of enamel jewellery from the subsequent Greek and Roman civilizations have been found. The Greek sculptors of the 4th and 5th centuries B.C., moreover, in many instances, made not only the eyes of enamel, as in the fine bronze head found at Anticythera (Cerigotto) in 1902, but in the colossal figure of Zeus for the temple at Olympia made by Pheidias the gold drapery was gorgeously enamelled with figures and flowers. This work, now destroyed, was in all probability the crowning triumph of a long series of essays in this material. The art of ancient Rome lacked the inspiration of Greece, being mainly confined to copying Greek forms and style, and enamelling was no exception. But the Roman and Etruscan glass has many beautiful qualities of form and colour that do not seem entirely borrowed, and the enamel work upon them so far as we can discern is of graceful design and rich colour.

The next time enamelling appears is in an oft-quoted passage (*c.* A.D. 240) from the writings of the great sophist Philostratus, who says (*Icones*, i. 28):—"It is said that the barbarians in the ocean pour these colours into bronze moulds, that the colours become as hard as stone, preserving the designs,"—a more or less inaccurate description of the process of *champlevé* (*see* description of enamel process appended). This has been understood (from an interpretation given to a passage in the commentary on it by Olearius) to refer to the Celts of the British Islands. It also goes to prove that enamelling was not practised at this day in Greece. We have no British enamels to show so early as this, but belonging to a later period, from the 6th to the 9th century, a number of fine gold and bronze ornaments, horse trappings, shields, fibulae and ciboria have been discovered of Celtic and Saxon make.

The close resemblance of method, style, design and colour would suggest that from Ireland the art was transferred to Byzantium. At all events it flourished there for several centuries. The finest known work belonging to this period is the Pala d'Oro at St. Mark's, Venice, believed to have been brought from Constantinople to Venice about 1105. This magnificent altar-piece is in *cloisonné* enamel. A typical example is the ciborium and chalice belonging to the South Kensington loan collection. The design entirely covers the whole of the surface in one rich mass composed of circular or vesica-shaped medallions filled with sacred subjects and foliated scrolls. These are engraved and enamelled, and the metal bands of the scrolls and figures are engraved and gilt. The characteristic colour scheme is composed almost wholly of primaries. Red, blue and yellow predominate, with a little white and black. Occasionally the secondaries, green and purple, are used, but through the whole period of Byzantine enamelling there is a total absence of what to-day is termed "subtle colouring." The arrangement of the enamels is also distinct, in that the divisions of the colours are not always made by the cloison, but are frequently laid in side by side without the adjoining colours mingling or running together whilst being melted. In most instances the enamels were made in separate little plates rudely fastened with nails, screws or rivets to a metal or wood foundation. The design and drawing of the figures in Byzantine enamels is similar to the mosaic and carving. The figures are treated entirely as decorations, with scarcely ever the least semblance of expression, although here and there an intention of piety or sorrow is to be descried through the awkward postures in which they are placed. In spite of this, the sense of decorative design, the simplicity of conception, the strength of the general character and the richness of the colour places this period as one of the finest that the art of enamelling has seen.

The next great application of these kinds of enamelling was at Cologne, for there we find not only the renowned work of Nicolas of Verdun, the altar front at Klosterneuberg, which consists of 50 plates in *champlevé* enamel, but in that Rhenish province there are many shrines of magnificent conception. From here the secrets of the craft were taken to Limoges, where the greatest activity was displayed. But no new method or distinct advance is to be noticed, during these successive revivals at Byzantium, Cologne or Limoges, and it is to early 14th-century Italy that we owe one of the most beautiful developments, that of the process subsequently called *basse-taille*, which signifies a low-cut relief upon which transparent enamel is fused.

Basse-taille demanded the highest knowledge of an artist with the consummate skill of both sculptor and enameller. Witness the superb gold cup, called the King's Cup, now in the British Museum, and the silver cup at King's Lynn. The first is in an excellent state of preservation, as it is upon gold, but the latter, like most of the ancient enamelling upon silver, has lost most of its enamel, due—the present writer, after much experiment, believes—to the impurity of the silver employed. The King's Cup (13th century) is one of the finest works in enamelling extant. It consists of a gold cup and cover, hammered out of pure gold; and around the bowl, base and cover there are bands of figures, illustrating scenes from the life of St. Agnes. The hands and faces are of pale amethyst which over the carved gold gives a beautiful flesh tone. The draperies are in most resplendent ruby, sapphire, emerald, ivory, black and orange. The stem was subsequently altered by an additional piece inserted and enamelled with Tudor roses.

The discovery about the same time of the process called *plique-à-jour* forms another most interesting and beautiful development. Owing to the difficulty of its manufacture and its extreme fragility there are very few examples left. One of the finest specimens is now at the Victoria and Albert Museum, South Kensington. It is in the form of two bands of emerald green enamel which decorate a silver beaker. They are in the form of little stained glass windows, the cloisons forming (as it were) the leads.

The end of the 15th century saw a revolutionary development. Until then enamelling had relied on the enclosing edges of the metal or the cloison to hold it to the metal ground and in part to preserve it in the shape of the pattern, much as a setting holds a jewel; all enamel had been sunk into cells or cloisons. Two discoveries were made; first, that enamel without enclosing ribbon could be fused on both sides of the metal object; secondly, that after an enamel had been fused to a surface of metal, another could be superimposed and fused to the first layer without any danger of separation from each or from the metal ground. In most of these enamel paintings the subject was laid on with a white enamel upon a dark ground. The white was modulated; so that possessing a slight degree of translucency, it was grey in the thin parts and white in the thick. Thus was obtained a certain amount of light and shade. This gave the process called *grisaille*. But strange to say, it was not until a later period that this was practised alone, and then the modelling of the figures and draperies became very elaborate. At first it was only done in a slight degree, just sufficiently to give expression and to add to the richness of the form. Probably the earliest painter in enamel was Nardon Pénicaud, many of whose works (one of them, dated 1503, is in the Cluny Museum) have been preserved. He had many followers, the most distinguished of whom was Léonard Limosin (*i.e.*, of Limoges). He excelled in portraiture. Examples of his work (between 1532 and 1574) are to be found in most of the larger public and private collections. Jean Pénicaud, Jean Court de Vigier, Pierre Raymond and Pierre Courteys excelled in *grisaille*.

MODERN EUROPEAN ENAMELS

The cultivated taste which prompted the acquisition and collection of the finer enamels such as those made in *basse-taille*, *plique-à-jour*, "Limoges" or painted and translucent enamels has always been confined to a few connoisseurs and patrons. And on the other hand the artists engaged in this work who have had the courage and persistence to carry on in spite of the failures incidental to such delicate and elaborate processes have been comparatively small in number at any time. So that it is not to be wondered at that the enamels of this character and standing have not been produced in quantities especially during recent years

THE PROCESS OF CLOISONNÉ

A cloisonné artist of Japan at work. The details of a design are outlined on a vase, with narrow bands or cloisons of metal (copper, silver or gold), which are soldered edgewise to the surface so as to make a pattern of shallow cells. Enamel colours, ground to a fine powder, and moistened, are then tightly packed into the cells, to complete the design

when the patronage of the arts generally has fallen off to so great an extent. On the other hand the simpler processes of *cloisonné* and *champlevé* which lend themselves readily to the decoration and enrichment of metal surfaces have been employed in many diverse ways.

The application of enamel in these processes, which are the oldest and most primitive, has been largely due to the tuition in the classes held in the Schools of Art, the municipal and County Council schools and the technical institutes in Great Britain and Ireland and to similar educational bodies which foster the Arts and Crafts in Europe, America and the British colonies. There has been no attempt made at any advance on these ancient methods. The style and treatment both of the design and process remain the same; for indeed it would be difficult to improve them. The study of the old examples in these processes has carried with it the due appreciation of the suitability and character of the design.

The desire to perpetuate the names of the fallen in the World War brought about a demand for memorials in bronze, copper and silver on which the names of the men, the shields of their native towns, the badges of the regiments and companies and other heraldic achievements were done in enamel. These memorials are to be found in the cathedrals, churches, public buildings and the chapels of the colleges and universities. Besides which there has continued to be a considerable use of enamel on the altar ornaments of the churches. And the chalices, Bible covers and lamps have occasionally been enriched with either *cloisonné* or *plique-à-jour* enamels.

Again on the public presentation gifts of trophies, caskets, cups and other like ornaments there has been the suitable adornment of enamel designs. These various applications of enamel have constituted the main output of the art worker in enamels.

These examples, however, do not leap to the eye so much as the uses to which enamel has been put in commerce and trade. The enamelled iron advertisement plates have been exhibited on the walls and hoardings for many years, and have shown no advance in either technique or colour and design, but of recent years there has been a recognition of the beauty of the colour of enamel when artistically employed, and that this quality is of equal value to its permanence. It is effectively used in the lettering of the names of firms, of shopkeepers, with the trademark and emblems. These have been made in translucent enamel fused over copper and silver foil or in opaque enamels in the *champlevé* process. The great improvement in the design, spacing, drawing and form of the lettering is to be seen over shop and store windows replacing the ugly lettering and thus adding a refinement to the streets.

In the jewellers', gold and silversmiths', and fancy-goods shops a great advance had been made in the design and colour of the enamel decoration of gold and silver cigarette boxes, watches, the backs of brushes for the toilet table and indeed of all such things of a similar kind. There still remains a tendency to use an engine-turned ground on the silver and gold objects over which a clear transparent enamel has been fixed. The chief reason for the engine-turning is to give a "key" to the enamel by which it obtains a firmer hold on the metal than if it were applied to a smooth surface. Most of these articles are made in Russia, Czecho-Slovakia, Germany and Sweden.

Enamelling Processes.—The base of enamel is a clear, colourless, transparent vitreous compound called flux, which is composed of silica, minium and potash. This flux or base—termed *fondant* in France—is coloured by the addition of oxides of metals while in a state of fusion, which stain the flux throughout its mass. Enamels are either hard or soft, according to the proportion of the silica to the other parts in its composition. They are termed hard when the temperature required to fuse them is very high. The harder the enamel the less liable is it to be affected by atmospheric agencies, which in soft enamels produce a decomposition of the surface first and ultimately of the whole enamel. Pure—or almost pure—metals are in most respects the best to receive and retain the enamel. Enamels composed of a great amount of soda or potash, as compared with those wherein red lead is in greater proportion, are more liable to crack and are less cohesive. It is better not to use silver as a base, although it is capable of reflecting a higher and more brilliant white light than any other metal. Fine gold and pure copper as thin as possible are the best metals upon which to enamel. If silver is to be used, it should be fine silver, treated in the methods called *champlevé* and *cloisonné*.

The brilliancy of the substance enamel depends upon the perfect combination and proportion of its component parts. The intimacy of the combination depends upon an equal temperature being maintained throughout its fusion in the crucible. For this purpose it is better to obtain a flux which has been already fused and most carefully prepared, and afterwards to add the colouring oxides, which stain it dark or light according to the amount of oxide introduced. Many of the enamels are changed in colour by the difference of the proportion of the parts composing the flux, rather than by the change of the oxides. For instance, turquoise blue is obtained from the black oxide of copper by using a comparatively large proportion of carbonate of soda, and a yellow green from the same oxide by increasing the proportionate amount of the red lead. All transparent enamels are made opaque by the addition of calx, which is a mixture of tin and lead calcined. White enamel is made by the addition of stannic and arsenious acids to the flux. The amount of acid regulates the density or opacity of the enamel.

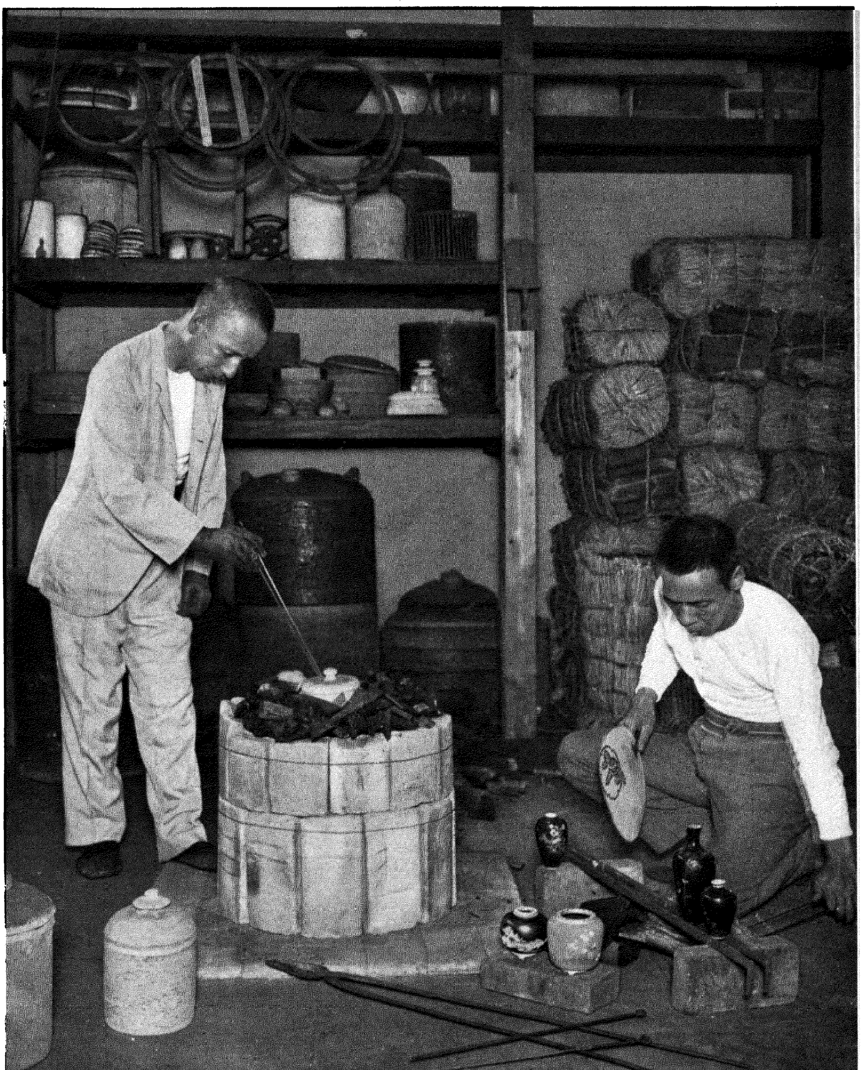
After the enamel has been procured in the ump, the next stage in the process, common to all methods of enamelling, is to pulverize it. To do this properly the enamel must first be placed in an agate mortar and covered with water; next, with a wooden mallet a number of sharp blows must be given to a pestle held vertically over the enamel, to break it; then holding the mortar firmly in the left hand, the pestle must be rotated with the right, with as much pressure as possible on the enamel, grinding it until the particles are reduced to a fine grain. The powder is then subjected to a series of washings in distilled water, until all the floury particles are removed. After this the metal is cleaned by immersion in acid and water. For copper, nitric acid is used; for silver, sulphuric, and for gold, hydrochloric acid. All trace of acid is then removed, first by scratching with a brush and water, and finally by drying in warm oak sawdust. After this the pulverized enamel is carefully and evenly spread over those parts of the metal designed to receive it, in sufficient thickness just to cover them and no more. The piece is then dried in front of the furnace, and when dry is placed gently on a fire-clay or iron *planche*, and introduced carefully into the muffle of the furnace, which is heated to a bright pale red. It is now attentively watched until the enamel shines all over, when it is withdrawn from the furnace. The firing of enamel, unlike that of glass or pottery, takes only a few minutes, and in nearly all processes no annealing is required.

The following are the different modes of enamelling: *champlevé, cloisonné, basse-taille, plique-à-jour, painted enamel, encrusted* and *miniature-painted*. These processes were known at successive periods of ancient art in the order in which they are named. To-day they are known in their entirety. Each has been largely developed and improved. No new method has been discovered, although variations have been introduced into all. The most important are those connected with painted enamels, encrusted enamels and *plique-à-jour*.

Champlevé enamelling is done by cutting away troughs or cells in the plate, leaving a metal line raised between them, which forms the outline of the design. In these cells the pulverized enamel is laid and then fused; afterwards it is filed with a corundum file, then smoothed with a pumice stone and polished by means of crocus powder and rouge.

In *cloisonné enamel*, upon a metal plate or shape, thin metal strips are bent to the outline of the pattern, then fixed by silver solder or by the enamel itself. These strips form a raised outline, giving cells as in the case of *champlevé*. The rest of the process is identical with that of *champlevé* enamelling.

The *basse-taille* process is also a combination of metal work in the form of engraving, carving and enamelling. The metal, either silver or gold, is engraved with a design, and then carved into a bas-relief (below the general surface of the metal like an Egyptian



PHOTOGRAPH, HERBERT G PONTING, F.R.P.S.

FIRING THE ENAMELS

Japanese cloisonné artists firing enamels in a charcoal fire. This process is repeated several times because of the shrinkage of the enamel under heat and the pitting which takes place. When the firing has been satisfactorily completed the surface of the vase is ground down to an even texture with pumice and polished with charcoal, and the metal surfaces of the cloisons, now clearly visible, are gilded

bas-relief) so that when the enamel is fused it is level with the uncarved parts of the metals, and the design shows through the transparent enamel.

Plique-à-jour enamelling is done in the same way as *cloisonné* enamelling, except that the wires or strips of metal which enclose the enamel are not soldered to the metal base, but are soldered to each other only. Then these are simply placed upon a sheet of platinum, copper, silver, gold or hard brass, which, after the enamel is fused and sufficiently annealed and cooled, is easily removed.

Painted enamels are different from any of these processes both in method and in result. The metal in this case is either copper, silver or gold, but usually copper. It is cut with shears into a plate of the size required, and slightly domed with a burnisher or hammer, after which it is cleaned by acid and water. Then the enamel is laid equally over the whole surface both back and front, and afterwards "fired." The first coat of enamel being fixed, the design is carried out, first by laying it in white enamel or any other which is opaque and most advantageous for subsequent coloration.

In the case of a *grisaille painted enamel* the white is mixed with water or turpentine, or spike oil of lavender, or essential oil of petroleum (according to the taste of the artist) and the white is painted thickly in the light parts and thinly in the grey ones over a dark ground, whereby a slight sense of relief is obtained and a great degree of light and shade.

In *coloured painted enamels* the white is coloured by transparent enamels spread over the *grisaille* treatment, parts of which when fired are heightened by touches of gold, usually painted in lines. Other parts can be made more brilliant by the use of foil, over which the transparent enamels are placed and then fired.

Miniature enamel painting is not true enamelling, for after the white enamel is fired upon the gold plate, the colours used are not vitreous compounds—not enamels in fact—as is the case in any other form of metal enamelling; but they are either raw oxides or other forms of metal, with a little flux added, not combined. These colours are painted on the white enamel, and afterwards made to adhere to the surface by partially fusing the enamel, which when in a state of partial fusion becomes viscous.

Amongst the chief workers in the modern revival are Claudius Popelin, Alfred Meyer, Paul Grandhomme, Fernand Thesmar, Hubert von Herkomer, Alexander Fisher, P. Oswald Reeves and Harold Stabler. The work of Claudius Popelin is characterized by good technical skill, correctness and a careful copying of the old masters. Consequently it suffers from a lack of invention and individuality. His work was devoted to the rendering of mythological subjects and fanciful portraits of historical people. Alfred Meyer and Grandhomme are both accomplished and careful enamellers; the former is a painter enameller and the author of a book dealing technically with enamelling. Grandhomme paints mythological subjects and portraits in a very tender manner, with considerably more artistic feeling than either Meyer or Popelin. There is a specimen of his work in the Luxemburg Museum. Fernand Thesmar is the great reviver of *plique-à-jour* enamelling in France. Specimens of his work are possessed by the art museums throughout Europe, and one is to be seen in the Victoria and Albert Museum, London. They are principally valued on account of their perfect technical achievement. Lucien Falize was an employer of artists and craftsmen, and to him we are indebted for the production of specimens of *basse-taille* enamel upon silver and gold, as well as for a book reviewing the revival of the art in France, bearing particularly on the work of Claudius Popelin. Until within recent years there was a clear division between the art and the crafts in the system of producing art objects. The artist was one person and the workman another. It is now acknowledged that the artist must also be the craftsman, especially in the higher branches of enamelling. Falize initiated the production of a gold cup which was enamelled in the *basse-taille* manner. The band of figures was designed by Olivier Merson, the painter, and carved by a metal carver and enamelled by an enameller, both able craftsmen employed by Falize. Other pieces of enamelling in *champlevé* and *cloisonné* were also produced under his supervision but on this system; therefore lacking the one quality which would make them complete as an expression of artistic emotion by the artist's own hands. René Lalique is among the jewellers who have applied enamelling to their work in a peculiarly technically perfect manner.

BIBLIOGRAPHY.—Among older books on enamelling, apart from the works of Neri and Benvenuto Cellini, are J.-P. Ferrand, *L'Art du feu, ou de peindre en émail* (1721); Labarte, *Recherches sur la peinture en émail* (Paris, 1856); Marquis de Laborde, *Notice des émaux du Louvre* (Paris, 1852); Reboulleau, *Nouveau manuel complet de la peinture en verre, sur porcelaine et sur émail* (ed. by Magnier, Paris, 1866); Claudius Popelin, *L'Émail des peintres* (Paris, 1866); Emil Molinier, *Dictionnaire des émailleurs* (1885). Among useful recent books are H. Cunynghame's *Art of Enamelling on Metals* (1906); L. Falize, *Claudius Popelin et la renaissance des émaux peints;* L. Dalpayrat, *Limoges Enamels;* Alexander Fisher, *The Art of Enamelling upon Metal* (1906, "The Studio," London). (A. FR.)

II. CHINESE AND JAPANESE ENAMELS

Enamels do not appear to have reached China until long after they were to be found throughout Europe. The Chinese make no claim to their invention; but, on the contrary the native term, "*Fu-lin* ware" (hence *Fa-lan*), directly suggests an origin in the eastern Roman provinces, that name having been applied to the Byzantine empire by Chinese historians as early as the 7th century. The derivation of the word has been the subject of controversy and is uncertain; but all authorities are agreed as to the western origin of the art; which was, in all probability, introduced into China by Arab traders, or by travelling craftsmen working their way eastwards as opportunity arose of plying their craft profitably. Glass, which in China was also of alien origin, was imported from the Roman empire certainly as early as the 3rd century A.D.; but it was not until the reign of T'ai Wu (424–452) of the northern Wei dynasty that craftsmen from an Indo-Scythian kingdom on the north-west border of India came to the Wei capital in Shansi and succeeded in making excellent opaque glass of various colours from local minerals.

Although the Chinese were thus informed as to the production of an essential material for the making of enamels and were already most highly skilled in the working of bronzes and other metals, it is remarkable that there appears to have been no development of the art of enamelling at least until the 13th century, when the Mongolian conquests introduced into the Far East so many arts hitherto unknown. A record exists, in the *Ko ku yao lun*, a book on antiquities published in 1387, of the production on a large and varied scale of enamelled ware which "resembles the cloisonné work of Fo-lang." This is herein termed also *Kuei kuo yao*, ware of the devils' country. It also states that natives of Yunnan have established factories for this ware in Peking and that the enamels made at the provincial capital, Yunnan-fu, are "fine, lustrous and beautifully finished." It appears therefore that the *Ta shih yao* or Arabian (so-called) enamel ware was well established in China at this period; and that Byzantine work of similar character was also so well known as to invite comparison with the native product and that, as pointed out by M. Paléologue, "the workmanship (of the Chinese enamels) presents occasionally, in fact, striking resemblances with certain enamels of the Byzantine School: the mixture of different enamels inside the wall of the same cell, the employment of gold encrustations in the treatment of the figures and hands, etc."

From the technical point of view, Chinese enamels fall into three categories—cloisonné, champlevé and painted. In none does the technique vary appreciably from that employed in western countries.

Cloisonné.—In *cloisonné*, the outlines of practically every detail of the design are defined with narrow bands or ribbons of metal—copper, silver or gold—soldered edgewise to the base, in such a way as to cover the whole surface to be decorated, with shallow cells sometimes called *cloisons*, but this term is more correctly employed to designate the bands themselves. These are then filled with the appropriate enamel colours, ground to a fine powder, moistened and tightly packed into their respective cells. "The piece," says Dr. S. W. Bushell, "is usually fired in the open courtyard, protected only by a primitive cover of iron network,

PAINTED, CLOISONNÉ AND CHAMPLEVÉ CHINESE ENAMELS OF THE XVIII. AND XIX. CENTURIES

1. Imperial teapot of Peking enamel painted, Ch'ien Lung period (1736–95)
2. Round screen of Peking enamel, with a landscape design
3. Incense burner of cloisonné on copper, in three parts, bowl, ring and cover. It is decorated with floral designs and openwork on turquoise blue ground; height, 16 inches. 19th century
4. Incense burner in cloisonné with stand and cover of same material and design. Turquoise blue ground; 24½ x 12½ inches. Ch'ien Lung period
5. Large dish of Peking enamel decorated with Taoist sages walking. Ch'ien Lung period.
6. Cloisonné snuff bottle of turquoise blue and white enamel ground, with coral stopper; height, 2-3/7 inches. Ch'ien Lung period
7. Seated figures and tripod censer of cloisonné. The figures, 37 inches in height, are on garden seats, also in cloisonné, and represent an empress (left) and a princess, probably of the Ch'ien Lung period. The robes of the former are executed with designs on chocolate colour ground and those of the latter on a ground of blue and imperial yellow. Faces and hands are gilt. The censer is enamelled in both cloisonné and champlevé on turquoise blue ground. The handles are of archaic sceptre-shape and the cover is surmounted by a gilt bronze finial; height 36 inches. Era of Tao-kuang (1821–50)
8. Gourd-shaped cloisonné snuff bottle, with metal and enamel stopper, on wood stand; height, 2⅞ inches. Ch'ien Lung period

the charcoal fire being regulated by a number of men standing round with large fans in their hands." This process has to be repeated several times, on account of the shrinkage, under heat, of the enamel, and the pitting which also takes place. When the whole surface is thus satisfactorily covered in this manner it is ground down to an even texture with pumice stone and polished with charcoal; the metal surfaces of the cloisons, now clearly visible being gilded, as well as those parts of the object which have not been adorned with enamel; for instance, the neck, rims and foot of a vase as well as any decoration in relief which projects beyond the enamelled surface.

The earliest examples of cloisonné enamel that can be authentically associated with the Far East, are mirrors in the *Shôsō in* ("lonely building"), at Nara in Japan. The backs of these have cloisonné work, somewhat crude in character. There is no doubt that these and other objects in the collection were deposited in the *Shōsō in* in the year 756 by Kōmyō-Kōgō, widow of the Emperor Shomo-Tennō (724–749), with other treasures collected during his life. We have here, therefore, authentic examples of the art that must date back at least to the T'ang dynasty, and may, as is certainly the case with some other objects in the collection, be of Chinese workmanship. It is generally agreed that they are neither Japanese nor Byzantine. So far as is known at present, the sequence of Chinese enamels with which we are acquainted begins, however, only in the Yuan period; and the earliest recorded marks belong to the reign of the last emperor of that dynasty (1341–1367). The great period of the production is certainly that of the Ming dynasty which followed and existed until 1643.

The mark most commonly found within this epoch is that of the Ching T'ai reign (1450–1456); so Dr. Bushell suggests that there must have been a great revival of the art at this time, as even in his day, the term *Ching T'ai Lan* was "commonly used in Peking as a general synonym for cloisonné enamels." He points out the significance of the fact that this reign covers the time of the last siege and capture of Constantinople by the Turks (1453) when some of the craftsmen then dispersed may have even penetrated to China. However this may be, the Ming enamels, bold in design, with fine depth and purity of colour, were never surpassed in later epochs. The two shades of blue, a dark lapis-lazuli tone and a pale sky-blue with a very slight tinge of green, are particularly excellent. The red is of dark coral tint and the yellow full-bodied and pure. Greens derived from copper are sparingly used and Dr. Bushell states that *rouges d'or* (reds made of gold) do not come into the colour scheme at all. The black and white are the least successful; the former shallow and dull, the latter clouded and muddy. At the same time, an imperfection of technique is noted, a close examination revealing minute pitting in the enamels, due to inadequate packing of the material, and some want of polish in the surface. These technical defects, however, do not appreciably detract from the artistic value of the Ming enamels and, indeed, serve as a clue to their identification.

To the patronage of the Emperor K'ang Hsi (1662–1722) was due a great revival of art industries. In 1680 he established a whole series of imperial factories for this purpose, of which that devoted to the manufacture of enamels was No. 6 on the official list. Here he had made sets of incense vessels of cloisonné enamel for presentation to the numerous Buddhist temples in the neighbourhood of Peking, founded under his auspices and other objects for the honorific gifts which were characteristic of his enlightened reign. The enamels of his time were marked by an improvement in technical quality as compared with those of the Ming period, while the finer qualities of the latter are still, to a considerable extent, in evidence. In many cases the forms of ancient bronze vessels were revived for these purposes, with the addition of enrichments in enamel. The style of this reign persisted during that of K'ang Hsi's successor, Yung Chêng (1723–1735); while the long period on the throne occupied by Ch'ien Lung (1736–1795) was marked, as in the case of many other industrial arts, by a further perfection of technique, but with the loss of much of the vigour of design and breadth of execution that distinguished the products of earlier periods. Modern enamels, chiefly imitations of older work, are more hurriedly made and not so well finished. The quality of the gilding especially is far below that of the older productions.

Champleve.—In *champlevé enamels,* cloisons are not used, the hollows to be filled with colour being cut out of the metal with graving tools. Otherwise the process is similar to that last described. It is probably the oldest method of enamelling known, and there is no evidence as to the date of its introduction into China, though some of the most ancient examples extant belong to this class. The general trend of design and execution, historically, is much the same as that of cloisonné. Examples in which both methods are employed are not infrequent.

Painted Enamels.—The *painted enamels* of China, generally known from the principal seat of their manufacture as *Canton enamels,* are practically identical in technique with the Limoges and other painted enamels of Europe. Specimens of these are known to have been taken to China by the missionaries of the late 17th and 18th centuries, and not only to have exercised direct influence on the Chinese ware, but also, in some cases, to have been copied. Representations of European subjects, copies of engravings and armorial decorations, are also found there. Painted enamels are termed by the Chinese *Yang t'zu* (literally "foreign porcelain"), the palette of colours used being the same as with enamelled porcelain though, in the case of enamels it is termed *Yang ts'ai* (foreign colours). A ground of opaque enamel, generally white, is laid on the copper; and on this the colours are superimposed and fired. Owing to the soft nature of the ground, these sink in and are incorporated with it, producing a loss of brilliance, which, as admitted by the Chinese, renders them inferior to enamelled porcelain with which they may well be compared. The earliest dated example of Canton enamel consists of a set of objects inscribed *Yung chêng yu chih* (1723–1735) made to imperial order. Although imitations have continued to be made, nothing of real quality in this style was produced after the termination of the reign of Ch'ien Lung in 1795. The method has always been looked upon by the Chinese as in alien taste; a writer of 1782 (quoted by Bushell) remarks, "They are only fit for use as ornaments of ladies' apartments—not at all for the chaste furniture of the library of a simple scholar." Enamels of this kind were also made, with characteristic decoration, for the Siamese market.

Translucent (as opposed to opaque) enamels were occasionally made by Chinese artisans. Important pieces are rare, but sometimes of fine quality, a deep blue, obtained from a native cobaltiperous ore of manganese, and a pale turquoise blue from copper being especially successful. This method more often appears in conjunction with gold and silver in Chinese jewellery; in which, also, imitations, in enamel, of real gems are frequently employed.

Japanese Enamels.—The examples of enamel in the imperial treasury at Nara, Japan, have already been referred to; and it may now be repeated that they cannot be attributed to Japanese craftsmanship. No examples of authentic enamels of Japanese origin that can be dated earlier than the end of the 16th century seem to exist. The western influence which promoted the art in China does not appear to have penetrated to Japan; the first Japanese appearance of the art seems to have been in the form of the decoration of sword furniture by the founders of the Hirata family who worked at Kyōto under the patronage of the Tokugawa Shōgun, Iyeyasu about the year 1611. They made use, on a small scale, both of the cloisonné and champlevé methods. A dull green was one of the first colours obtained. The range of colours was afterwards extended with a white of good quality. There was no further development of importance until the 19th century, when Kaji Tsunikichi (born A.D. 1802) of Nagoya established in that city an important and successful manufacture of cloisonné which obtained a considerable vogue especially among foreigners. On this basis further developments have taken place of considerable interest.

Modern Japanese artists have modified the cloisonné process with remarkable ingenuity and have produced work of great interest, in which the cloisons are sometimes completely veiled, the resultant effect being that of enamelled porcelain with realistic designs of flowers, etc., and a wide and almost unrestricted range

THE CLOISONNÉ PROCESS AND CHINESE CLOISONNÉ ENAMELS OF THE XV.–XVIII. CENTURIES

1 and 2. *Stages in the process of cloisonné enamelling, showing first, the* metal plate on which the design is executed by soldering thin metal bands or *cloisons* to the base to form shallow cells (second step). These cells are filled with powdered enamel colours, and the piece is then fired and polished. 3. Beaker-shaped imperial vase with gilt bronze dragon and phoenix handles. Turquoise blue ground sustaining flowers and vines; height 41½ inches. Reign of Ch'ing Tai (1450–56), Ming dynasty. 4. Trumpet-shaped vase decorated with eyes and cloud forms on turquoise blue ground; height, 14½ inches. Ming dynasty. 5. Beaker-shaped vase with floriated *ornament*, scrolls and palmettes; height, 21½ inches. K'ang-hsi period (1662–1722). 6. Twin vases enamelled in green and joined by bronze ornaments, signifying the unity of the universe; height, 25½ inches. Era of Yung-Cheng (1723–35). 7. Jui sceptre (repaired); length, 15¾ inches. K'ang-hsi period. 8. Dove-shaped altar wine vessel on wheels, patterned after a type of ancient vessel used at rituals. Besides the conventional ornamentation, the decoration consists of scrolls and various designs, such as monsters' heads, copied from very old bronzes; height, 22 inches. K'ang-hsi period

of colour. Namikawa of Tōkyō has been one of the most successful of these. A Kyōto artist of the same name has worked with credit in true *cloisonné*. J. Ando of Nagoya has obtained novel effects by the use of translucent enamel on a silver basis. These developments have carried the art of enamel very far from the old traditions, but, while the skill and ingenuity of technique they evince may be appreciated, it cannot be said that in decorative value they compare with the older Chinese tradition. During the 19th century, the Japanese produced many imitations of the latter; which, for a time gave rise to quite a false appreciation of their place in the history of the art.

ENAMELLED IRON WARE: *see* Porcelain Enamelling.

ENCAENIA, a festival commemorating a dedication, in Greek τὰ ἐγκαίνια, particularly used of the anniversary of the dedication of a church (*see* Dedication). The term is also used at the University of Oxford of the annual Commemoration, held in June, of founders and benefactors (*see* Oxford).

ENCAMPMENT: *see* Camp.

ENCAUSTIC PAINTING. The name *encaustic* (from the Greek for "burnt in") is applied to paintings executed with vehicles in which wax is the chief ingredient. The term was appropriately applied to the ancient methods of painting in wax, because these required heat to effect them. Wax may be used as a vehicle for painting without heat being requisite; nevertheless the ancient term *encaustic* has been retained, and is indiscriminately applied to all methods of painting in wax. The durability of wax, and its power of resisting the effects of the atmosphere, were well known to the Greeks, who used it for the protection of their sculptures. As a vehicle for painting it was commonly employed by them and by the Romans and Egyptians; but in recent times it has met with only a limited application. Of more modern encaustic paintings those by Schnorr in the Residenz at Munich are the most important. Modern paintings in wax, in their chromatic range and in their general effect, occupy a middle place between those executed in oil and in fresco. Wax painting is not so easy as oil, but presents fewer technical difficulties than fresco.

Ancient authors often make mention of *encaustic*, which, if it had been described by the word *inurere*, to burn in, one might have supposed to have been a species of enamel painting. But the expressions "incausto pingere," "pictura encaustica," "ceris pingere," "pictura inurere," used by Pliny and other ancient writers, make it clear that some other species of painting is meant. Pliny distinguishes three species of encaustic painting. In the first they used a stylus, and painted either on ivory or on polished wood, previously saturated with some certain colour; the point of the stylus or stigma served for this operation, and its broad or blade end cleared off the small filaments which arose from the outlines made by the stylus in the wax preparation. In the second method it appears that the wax colours, being prepared beforehand, and formed into small cylinders for use, were smoothly spread by the spatula after the outlines were determined, and thus the picture was proceeded with and finished. By the side of the painter stood a brazier which was used to heat the spatula and probably the prepared colours. This is the method which was probably used by the painters who decorated the houses of Herculaneum and of Pompeii, as artists practising this method of painting are depicted in the decorations. The third method was by painting by a brush dipped into wax liquefied by heat; the colours so applied attained considerable hardness, and could not be damaged either by the heat of the sun or by the effects of sea-water. It was thus that ships were decorated; and this kind of encaustic was therefore styled "ship-painting."

About the year 1749 Count Caylus and J. J. Bachelier, a painter, made some experiments in encaustic painting, and the count undertook to explain an obscure passage in Pliny, supposed to be the following (xxxv. 39):—"Ceris pingere ac picturam inurere quis primus excogitaverit non constat. Quidam Aristidis inventum putant, postea consummatum a Praxitele; sed aliquanto vetustiores encausticae picturae exstitere, ut Polygnoti et Nicanoris et Arcesilai Pariorum. Lysippus quoque Aeginae picturae suae inscripsit ἐνέκαυσεν, quod profecto non fecisset nisi encaustica inventa." There are other passages in Pliny bearing upon this subject, in one of which (xxi. 49) he gives an account of the preparation of "Punica cera." The nature of this Punic wax, which was the essential ingredient of the ancient painting in encaustic, has not been definitely ascertained. The chevalier Lorgna, who investigated the subject in a small but valuable tract, asserts that the *nitron* which Pliny mentions is not the nitre of the moderns, but the *natron* of the ancients, viz., the native salt which is found crystallized in Egypt and other hot countries in sands surrounding lakes of salt water. This substance the Carthaginians, according to Pliny, used in preparing their wax, and hence the name Punic seems to be derived. Lorgna made a number of experiments with this salt, using from three to twenty parts of melted white wax with one of natron. He held the mixture in an iron vessel over a slow fire, stirring it gently with a wooden spatula, till the mass assumed the consistency of butter and the colour of milk. He then removed it from the fire, and put it in the shade in the open air to harden. The wax being cooled liquefied in water, and a milky emulsion resulted from it like that which could be made with the best Venetian soap.

Experiments, it is said, were made with this wax in painting in encaustic in the apartments of the Count Giovanni Battista Gasola by the Italian painter Antonio Paccheri, who dissolved the Punic wax when it was not so much hardened as to require to be "igni resoluta," as expressed by Pliny, with pure water slightly infused with gum-arabic, instead of sarcocolla, mentioned by Pliny. He afterwards mixed the colours with this wax so liquefied as he would have done with oil, and proceeded to paint in the same manner; nor were the colours seen to run or alter in the least; and the mixture was so flexible that the pencil ran smoother than it would have done with oil. The painting being dry, he treated it with caustic, and rubbed it with linen cloths, by which the colours acquired peculiar vivacity and brightness.

LATER METHODS

About the year 1755 further experiments were made by Count Caylus and several French artists. One method was to melt wax with oil of turpentine as a vehicle for the colours. It is well known that wax may be dissolved in spirit and used as a medium, but it dries too quickly to allow of perfect blending, and would by the evaporation of the spirit be prejudicial to the artist's health. Another method suggested about this time, and one which seems to tally very well with Pliny's description, is the following. Melt the wax with strong solution of salt of tartar, and let the colours be ground up in it. Place the picture when finished before the fire till by degrees the wax melts, swells, and is bloated up upon the picture; the picture is then gradually removed from the fire, and the colours, without being injuriously affected by the operation of the fire, become unalterable, spirits of wine having been burnt upon them without doing the least harm. Count Caylus's method was different, and much simpler: (1) the cloth or wood designed for the picture is waxed over, by rubbing it simply with a piece of beeswax; (2) the colours are mixed up with pure water; but as these colours will not adhere to the wax, the whole ground must be rubbed over with chalk or whiting before the colour is applied; and (3) when the picture is dry it is put near the fire, whereby the wax is melted and absorbs the colours. It must be allowed that nothing could well be simpler than this process, and it was thought that this kind of painting would be capable of withstanding the weather and of lasting longer than oil painting. This kind of painting has not the gloss of oil painting, so that the picture may be seen in any light, a quality of the very first importance in all methods of mural painting. The colours too, when so secured, are firm, and will bear washing, and have a property which is perhaps more important still, viz., that exposure to smoke and foul vapours merely leaves a deposit on the surface without injuring the work. The "encausto pingendi" of the ancients could not have been enamelling, as the word

"inurere," taken in its rigorous sense, might at first lead one to suppose, nor could it have been painting produced in the same manner as encaustic tiles or encaustic tesserae; but that it must have been something akin to the count's process would appear from the words of Pliny already quoted, "Ceris pingere ac picturam inurere."

Werner of Neustadt found the following process very effectual in making a wax emulsion with water. For each pound of white wax he took twenty-four ounces of potash, which he dissolved in two pints of water, warming it gently. In this lye he boiled the wax, cut into little bits, for half an hour, after which he removed it from the fire and allowed it to cool. The wax floated on the surface of the liquor in the form of a white saponaceous matter; and this being triturated with water produced a sort of emulsion, which he called wax milk, or encaustic wax. This preparation may be mixed with all kinds of colours, and consequently can be applied in a single operation.

Mrs. Hooker of Rottingdean, at the end of the 18th century, made many experiments to establish a method of painting in wax, and received a gold palette from the Society of Arts for her investigations in this branch of art. Her account is printed in the tenth volume of the Society's Transactions (1792), under the name of Miss Emma Jane Greenland. Modern experiments have shown that it is quite possible to paint with the brush with pigments mixed with melted wax if the panel is kept warm. Each stroke must be laid directly where and as required. ENCEINTE, a French term used technically in fortification for the inner ring of fortifications surrounding a town. (Lat. *in*, within, *cinctus*, girdled; to be distinguished from the word meaning "pregnant," from *in*, not, and *cinctus, i.e.*, with girdle loosened.) Strictly the term was applied to the continuous line of bastions and curtains forming the "body of the place," this last expression being often used as synonymous with *enceinte*. The outworks, however, close to the enceinte were not considered as forming part of it. In modern fortification the enceinte is usually simply the innermost continuous line of fortifications. In architecture an enceinte is the close or precinct of a cathedral, abbey, castle, etc.

ENCEPHALITIS LETHARGICA, a disease of the brain characterized by coma (sleepy sickness). The virus is unknown. Filtrable organisms have been described and also the transmission of the disease by injection of nervous tissues, but these experiments are at present inconclusive. The incubation period is estimated at two weeks. The degree of infectivity must be small. The duration of infectivity and of the persistence of the virus in the body are unknown. Apparently the virus may lie quiescent and return to activity after long periods, since late manifestations have been known to develop after two to four years, sometimes after apparent cure in the intervals. No age is immune to infection.

Symptoms.—It is very difficult to classify the different cases. The best scheme provisionally is that of MacNalty. This classifies the cases under the following main types:

1. In which there is general disturbance of the functions of the central nervous system but without localization.

2. In which, in addition to general disturbance, there are various localizations in the central nervous system. The most frequent of these are affections of the third pair of cranial nerves, but no portion of the nervous system is immune.

3. Mild or so-called abortive cases (*formes frustes*).

The clinical manifestations are very variable and complex and are best classified, according to Walshe's scheme into general and nervous.

I. General: (1) negative, (2) positive.
II. Focal: (1) negative, (2) positive.

The positive symptoms denote exaltation of function due either to irritation of nervous tissue or to a loss of the control exerted normally by the higher centres of the brain; negative symptoms denote depression or loss of function due principally to destruction of nervous tissue.

The onset of the disease may be sudden or insidious. Occasionally the onset is extraordinarily sudden, the patient falling asleep almost without warning or sometimes becoming delirious. More frequently it is insidious either with the development of drowsiness or with more general symptoms. The general symptoms are not in themselves distinguishable from those of other conditions. Headache is common, and nausea and vomiting are frequent without being very severe. The temperature is very variable. It may be about 102° F. at the onset, falling after a few days, or it may be normal at the onset and rise later in the first week. A persistent rise is a serious sign. Some cases are apyrexial throughout. There is no characteristic eruption. In the mild and abortive types the general condition may suggest influenza and the nature of the illness only be recognized long subsequently by the development of characteristic late manifestations. Most cases undoubtedly commence with some grade of the characteristic symptoms of lethargy and double vision.

Lethargy.—The depth of this varies from apathy or drowsiness to deep sleep. The patient can usually be roused and may then answer questions with unexpected clearness. Occasionally the lethargy gradually deepens to stupor and fatal coma. Most commonly the lethargy lasts for two to three weeks, but it varies from a few days to several months. Rarely is it completely absent. Occasionally there may be somnolence by day and insomnia by night.

Double Vision.—Diplopia, or double vision, also occurs in the majority of cases, and is due to some form of paralysis of the ocular muscles. Other ocular manifestations may occur, such as ptosis or drooping of the eye-lids. The pupils may exhibit every possible variation from the normal in size, shape and reactions. Coarse nystagmoid movements are also common. Optic neuritis is never marked and a definite degree of swelling of the optic disc suggests an error in the diagnosis.

Nervous Symptoms.—Certain of the nervous manifestations which occur more commonly during convalescence or after the acute stages have passed will be referred to under the heading of "residual and late manifestations," but any of them may occur at the onset or at any point in the course of the disease.

The positive symptoms are represented by restlessness, delirium, acute mania and various degrees of excitement. General convulsions are not common but are usually fatal. Negative symptoms are represented by the characteristic lethargy referred to above.

Among the positive symptoms may be mentioned muscular pains which are occasionally severe and may simulate many diseases. In the positive group fall also the rigidity, Parkinsonism and the various involuntary movements which are referred to below among the late manifestations. The negative symptoms are represented by paralysis. The ocular manifestations have been mentioned above. Affection of the remaining cranial nerves may produce facial paralysis, difficulty in swallowing, rapid respiration and paralysis of the pharyngeal and laryngeal muscles. Aphasia and paralysis of the limbs may also occur. The deep reflexes are usually absent in the acute stages of severe cases, but there is no constant rule. The cerebro-spinal fluid may show a moderate increase in the number of lymphocytes but in at least one-third of the cases the fluid is normal.

Residual and Late Manifestations.—These are of the highest importance. The manifestations here referred to develop most frequently during convalescence, yet they may be present from the very outset of the disease, while in other cases long intervals, even of years, may elapse after the acute stages before their appearance. The initial attack may be so mild as to be overlooked at the time.

The most important of these manifestations are as follow:

The Parkinsonian Syndrome.—This is characterized by the

remarkable absence of facial expression which is termed the "Parkinsonian mask." There is also general muscular rigidity and a striking absence of slight and automatic movements. The general appearance resembles the condition known as paralysis agitans though the general effect is not quite identical.

Mental Changes.—These are of great importance from their frequency and character and are present to some extent in about 75% of cases. The changes may be of all grades, from slight weakness of the intellectual powers to definite dementia and insanity.

In adults the usual manifestation is a general weakness of the intellectual powers. The subject shows a marked lack of attention, concentration and initiative. Definite melancholia is not very common. There may be some irritability of temper but the excitement which occurs in children is not often seen in adults. Insomnia is a not infrequent symptom and may be very persistent. On the other hand there may be persistent drowsiness.

In children the mental changes are far more varied and of greater importance than in adults. As in adults the commonest effect is a weakening of the powers of concentration.

A second group, numerically smaller, is characterized by excitement. These children are usually under ten years of age. The excitement may be most marked during the night. For the time they are quite beyond control.

This group merges into a third group in which there are definite alterations in the moral character. Most of the children are between the ages of ten and 18 years. This group, though small, is important owing to the difficulty in dealing with the subjects. They become morally and sexually perverted. These changes are more common in children of families with a bad record mentally and criminally. There is a small group in which idiocy develops, usually in children under five years of age, and in a few cases there has been definite certifiable insanity. In addition to these mental changes Parkinsonism may be present and also the myoclonic and other movements described below. The treatment and especially the disposal of children in the second and third groups is a matter of great difficulty. Home surroundings are rarely suitable and the child will render ordinary family life impossible.

Involuntary Movements.—This group of "excito-motor" symptoms includes numerous varieties of involuntary movements and muscular contractions. Though they are more common late in the disease many of them occasionally occur at the onset. The most definite type is myoclonus which is characterized by short, rapid, rhythmic contractions of the muscles: a single muscle such as the diaphragm, or even a part of a single muscle may be affected. There is generally no movement at the joints, but in some cases the contractions are of a slow, rhythmic type and may lead to very complex movements. Various choreiform and athetoid movements are also met with. Tremors and tics of all types may also develop. Epidemic hiccough may be a variety.

Respiratory Abnormalities.—Rapid or deep breathing may be present, either continuously or in paroxysms at any period of the acuter stages. Violent spasmodic cough occasionally develops in children or sniffing and various respiratory spasms.

Paralysis.—The persistence of these is relatively uncommon. Diplopia is rarely permanent. Many nervous diseases, however, are occasionally simulated such as disseminated sclerosis. Numerous other late manifestations are observed more rarely. Among these may be mentioned obesity which is occasionally associated with polyuria, suggesting disturbance of the pituitary gland.

Progress and Prognosis.—A. J. Hall states as a rough approximation that of 100 cases, 25 recover completely, 25 die, and 50 have various residua of which at least 25 exhibit Parkinsonism. It is impossible to give a good prognosis during the acute stages in any case of encephalitis lethargica, owing to the fact that serious late manifestations may develop after a mild initial attack. Further, long quiescent periods may occur with subsequent recrudescence of activity and fresh manifestations. Such intervals may be several years, but the limit is at present unknown.

In the acute stages the outlook for life is bad with severe general symptoms, with a rapid onset, with high temperature, with acute delirium or with mania. Slight early symptoms may, however, also progress to serious grades. Deep, early lethargy is not necessarily a serious symptom. Early myoclonus and involuntary movements do not appear to be especially unfavourable. Most deaths occur within the first month and the prognosis for life improves after this.

With regard to special manifestations, the Parkinsonian syndrome may be recovered from partially or even completely when it develops early in the disease, but when it appears later it usually progresses and mental changes may also occur. The outlook in the cases with the severer mental changes is poor; recovery is rarely more than partial and relapses may follow.

The influence on pregnancy has been carefully studied by Hall. He considers that there is no evidence that pregnancy predisposes to infection with encephalitis lethargica, or that it is associated with a higher mortality or influences the course of the disease in any way. Residual manifestations, however, may be aggravated in a woman who has passed through an attack and become pregnant subsequently.

Diagnosis.—The disease is often easily recognized from the combination of lethargy and double vision. The milder forms, however, are easily overlooked at the onset and may frequently be unavoidably mistaken for influenza. When the more complex nervous symptoms are present the diagnosis may be of great difficulty. The conditions with which confusion most often occurs are meningitis (especially tuberculous), cerebral tumour, cerebral vascular lesions and cerebral syphilis.

Treatment.—This is on the general lines of treatment of acute febrile disease. Unfortunately there are no specific measures. The administration of hexamine may be recommended. The withdrawal of cerebro-spinal fluid by lumbar puncture is frequently performed but there is no evidence that it is beneficial.

Bibliography.—The monograph on Epidemic Encephalitis by A. J. Hall (John Wright and Sons, 1924) contains a complete and classified bibliography. The following articles include the earliest reports: C. von Economo, *Wien. Klin. Woch.*, xxx. 581 (1917); *Münch. Med. Woch.*, lxvi. 1311 (1919); A. J. Hall, *Lancet*, i. 568 (1918); W. Harris, *Lancet*, i. 586 (1918); E. F. Buzzard, *Lancet*, i. 616 (1918).

(H. L. T.)

ENCINA, JUAN DEL (1469–1529?), often called the founder of the Spanish drama. His *églogas* mark the transition from the purely ecclesiastical to the secular stage. The most characteristic are the *Auto del Repelón*, the *Égloga de Fileno* and *Plácida y Vitoriano*. Their intrinsic interest is slight, but they are historically important, for the lay pieces form a new departure, and the devout eclogues prepare the way for the *autos* of the 17th century. Encina's *Cancionero* (1496) contains also lyrical poems remarkable for their intense sincerity and devout grace.

See R. Mitjana, *Sobre Juan del Encina, músico y poeta* (Málaga, 1895).

ENCKE, JOHANN FRANZ (1791–1865), German astronomer, was born at Hamburg on Sept. 23, 1791. Matriculating at the University of Göttingen in 1811, he began to devote himself to astronomy under Carl Friedrich Gauss. In 1816, he was appointed assistant in the observatory of Seeberg near Gotha. There he completed his investigation of the comet of 1680, for which the Cotta prize was awarded to him in 1817; he correctly assigned a period of 71 years to the comet of 1812; and discovered the swift circulation of the remarkable comet which bears his name (*see* Comet). Eight masterly treatises on its movements were published by him in the Berlin *Abhandlungen* (1829–59). From a discussion of the transits of Venus in 1761 and 1769 he deduced (1822–24) a solar parallax of 8″·57, long accepted as authoritative. In 1822 he became director of the Seeberg observatory, and in 1825 was promoted to a corresponding position at Berlin. He died at Spandau on Aug. 26, 1865.

See C. Bruhns, *Johann Franz Encke, sein Leben und Wirken* (Leipzig, 1869), to which a list of his writings is appended. Also, *Month. Notices Roy. Astr. Society*, xxvi. 129; *V.J.S. Astr. Gesellschaft*, iv. 227; *Berlin. Abhandlungen* (1866), i., G. Hagen; *Sitzungsberichte*, Munich Acad. (1866), i. p. 395, etc.

ENCLAVE, a term signifying a country or, more commonly, an outlying portion of a country entirely surrounded by the territories of a foreign or other power. It is, however, generally used in a looser sense to describe a colony or other territory of a State, which, while possessing a seaboard, is entirely surrounded

landward by the possession of another power; or, if inland territory, nearly though not entirely so enclosed, *e.g.*, the Lado Enclave in equatorial Africa.

ENCOIGNURE, in furniture, literally the angle, or return, formed by the junction of two walls. The word is now chiefly used to designate a small armoire, commode, cabinet or cupboard made to fit a corner; a *chaise encoignure* is called in English a three-cornered chair. In its origin the thing, like the word, is French, and the delightful Louis XV. or Louis XVI. *encoignure* in lacquer or in mahogany elaborately mounted in gilded bronze was made in a vast variety of forms.

ENCORE (Fr. "again"), a word which has long been used by English audiences at musical performances to signify their desire for the repetition of a work.

ENCYCLICAL, an ecclesiastical epistle intended for general circulation, now almost exclusively used of such letters issued by the pope (from Late Lat. *encyclicus*, for *encyclius*=Gr. ἐγκύκλιος, from ἐν and κύκλος, "a circle"). The forms *encyclica* and *encyclic* are sometimes, but more rarely, used. The old adjectival use of the word in the sense of "general" (encircling) is now obsolete, though it survives in the term "encyclopaedia."

ENCYCLOPAEDIA. The Greeks seem to have understood by encyclopaedia (ἐγκυκλοπαιδεία, or ἐγκύκλιος παιδεία) instruction in the whole circle (ἐν κυκλῷ) or complete system of learning—education in arts and sciences. Thus Pliny, in the preface to his *Natural History*, says that his book treated of all the subjects of the encyclopaedia of the Greeks, "Iam omnia attingenda quae Graeci τῆς ἐγκυκλοπαιδείας vocant." The word encyclopaedia was probably first used in English by Sir Thomas Elyot. In his Latin dictionary, 1538, he explains "Encyclios et Encyclia, the cykle or course of all doctrines," and "Encyclopedia, that lernynge whiche comprehendeth all lyberall science and studies." The term does not seem to have been used as the title of a book by the ancients or in the middle ages. The edition of the works of Joachimus Fortius Ringelbergius, printed at Basle in 1541, is called on the title-page *Lucubrationes vel potius absolutissima* κυκλοπαιδεια. Paulus Scalichius de Lika, a Hungarian count, wrote *Encyclopaediae seu orbis disciplinarum epistemon* (1599). Alsted published in 1608 his *Encyclopaedia cursus philosophici,* and afterwards expanded this into his great work, noticed below, calling it without any limitation *Encyclopaedia,* because it treats of everything that can be learned by man in this life. This is now the most usual sense in which the word encyclopaedia is used—a book treating of all the various kinds of knowledge. The form "cyclopaedia" is not merely without any appearance of classical authority, but is etymologically less definite, complete and correct. For as Cyropaedia means "the instruction of Cyrus," so cyclopaedia may mean "instruction of a circle." Vossius says, "Cyclopaedia is sometimes found, but the best writers say encyclopaedia."

In a more restricted sense, encyclopaedia means a system or classification of the various branches of knowledge, a subject on which many books have been published, especially in Germany, as Schmid's *Allegemeine Encyklopädie und Methodologie der Wissenschaften* (Jena, 1810). In this sense the *Novum Organum* of Bacon has often been called an encyclopaedia. Fortunius Licetus, an Italian physician, entitled several of his dissertations on Roman altars and other antiquities encyclopaedias (as, for instance, *Encyclopædia ad Aram mysticam Nonarii* 1631), because in composing them he borrowed the aid of all the sciences. Encyclopaedia is often used to mean a book which is, or professes to be, a complete or very full collection or treatise relating to some particular subject, as Blaine's work, *The Encyclopaedia of Rural Sports; The Encyclopaedia of Wit; The Vocal Encyclopaedia,* a collection of songs, catches, etc. The word is frequently used for an alphabetical dictionary treating fully of some science or subject, as Murray, *Encyclopaedia of Geography;* Lefebvre Laboulaye, *Encyclopédie technologique: Dictionnaire des arts et manufactures;* the *Encyclopaedia Biblica.* Whether under the name of "dictionary" or "encyclopaedia" large numbers of this class of reference-work have been published. These are essentially encyclopaedic, being *subject books* and not *word-books.* The important books of this character are referred to in the articles dealing with the respective subjects.

Early Examples.—The great Chinese encyclopaedias are referred to in the article on CHINESE LITERATURE. It will be sufficient to mention here the *Wên hsien t'ung k'ao,* compiled by Ma Twa-lin in the 14th century, the encyclopaedia ordered to be compiled by the Emperor Yung-loh in the 15th century, and the *Ku chin t'u shu chi ch'êng* prepared for the Emperor K'ang-hi (d. 1721), in 5,020 volumes. A copy of this enormous work, bound in some 700 volumes, is in the British Museum.

THE MOST ANCIENT WORKS

The most ancient encyclopaedia extant is Pliny's *Natural History* in 37 books (including the preface) and 2,493 chapters, which treat of cosmography, astronomy and meteorology, geography, zoology (including man), the invention of the arts, botany, medicines, vegetable and animal remedies, medical authors and magic, metals, fine arts, mineralogy and mineral remedies. Pliny, who died A.D. 79, was not a naturalist, a physician or an artist, and collected his work in his leisure intervals while engaged in public affairs. He says it contains 20,000 facts (too small a number by half, says Lemaire), collected from 2,000 books by 100 authors. Hardouin has given a list of 464 authors quoted by him. His work was a very high authority in the middle ages, and 43 editions of it were printed before 1536.

Martianus Minneus Felix Capella, an African, wrote (early in the 5th century), in verse and prose, a sort of encyclopaedia, which is important from having been regarded in the middle ages as a model storehouse of learning, and used in the schools, where the scholars had to learn the verses by heart, as a text-book of high-class education in the arts. It is sometimes entitled *Satyra,* or *Satyricon,* but is usually known as *De nuptiis Philologiae et Mercurii,* though this title is sometimes confined to the first two books, a rather confused allegory ending with the apotheosis of Philologia and the celebration of her marriage in the Milky Way, where Apollo presents to her the seven liberal arts, who, in the succeeding seven books, describe their respective branches of knowledge from grammar to music (including poetry). The style is that of an African of the 5th century, full of grandiloquence, metaphors and strange words.

Isidore, bishop of Seville from 600 to 630, wrote *Etymologiarum libri XX.* (often also entitled his *Origines*) at the request of his friend Braulio, bishop of Saragossa, who after Isidore's death divided the work into books, dealing with a great variety of subjects, from grammar to war and games, from angel to animal, from mathematics to ships, buildings and garments. Isidore appears to have known Hebrew and Greek, and to have been familiar with the Latin classical poets, but he is a mere collector and his derivations are often absurd. He seldom mentions his authorities except when he quotes the poets or historians. Yet his work was a great one for the time, and for many centuries was a much valued authority and a rich source of material for other works, and he had a high reputation for learning both in his own time and in subsequent ages.

Hrabanus Maurus, whose family name was Magnentius, was educated in the abbey of Fulda, ordained deacon in 802, sent to the school of St. Martin of Tours, then directed by Alcuin, where he seems to have learned Greek, and is said by Trithemius to have been taught Hebrew, Syriac and Chaldee by Theophilus an Ephesian. He was ordained archbishop of Mainz in 847, and died in 856. He compiled an encyclopaedia *De universo* (also called *De universali natura, De natura rerum,* and *De origine rerum*) in 22 books. It is chiefly a rearrangement of Isidore's *Etymologies,* omitting a considerable part of it, and adding the meanings given in the Bible to the subject matter of the chapter; while things not mentioned in Scripture, especially such as belong to classical antiquity, are omitted, so that his work seems to be formed of two alternating parts. His arrangement of beginning with God and the angels long prevailed in methodical encyclopaedias. His omissions are characteristic of the diminished literary activity and more contracted knowledge of his time. His work was presented to Louis the German, king of Bavaria, at Hersfeld in Oct.

847, and was printed in 1473, probably at Venice, and again at Strasbourg by Mentelin about 1472–75.

Michael Constantine Psellus, the younger, wrote Διδασκαλία παντοδαπή, dedicated to the emperor Michael Ducas, who reigned 1071–78. It was printed by Fabricius in his *Bibliotheca Graeca* (1712), vol. v., in 193 chapters, each containing a question and answer. Beginning with divinity, it goes on through natural history and astronomy, and ends with chapters on excessive hunger, and why flesh hung from a fig-tree becomes tender.

Works of the Middle Ages.—The author of the most famous encyclopaedia of the middle ages was Vincent (*q.v.*) of Beauvais (*c.* 1190–*c.* 1264), whose work *Bibliotheca mundi* or *Speculum majus*, was the great compendium of mid-13th century knowledge. Vincent of Beauvais preserved several works of the middle ages and gives extracts from many lost classics and valuable readings of others, and did more than any other mediaeval writer to awaken a taste for classical literature. As Vincent did not know Greek or Arabic, he used Latin translations.

Brunetto Latini of Florence, the master of Dante and Guido Cavalcanti, while an exile in France between 1260 and 1267, wrote in French *Li Livres dou Tresor*. The Bible, natural history, ethics and politics, astronomy and geography are among the subjects covered. The last part, the most original and interesting of all, treats of the government of the Italian republics of the time. Brunetto's work was translated into Italian in the latter part of the 13th century by Bono Giamboni. Napoleon I. had intended to have the French text of the *Tesoro* printed with commentaries, and appointed a commission for the purpose. It was at last published in the *Collection des documents inédits* (1863), edited by Chabaille from 42 mss.

Bartholomew de Glanville, an English Franciscan friar, wrote about 1360 a most popular work, *De proprietatibus rerum*, in 19 books, beginning with God and the angels and ending with colours, scents, flavours and liquors, with a list of 36 eggs. There were 15 editions before 1500. An English translation was completed on Feb. 11, 1398, by John Trevisa, and printed by Wynkyn de Worde (? 1495).

Pierre Bersuire (Berchorius), a Benedictine, prior of the abbey of St. Eloi in Paris, where he died in 1362, wrote a kind of encyclopaedia, chiefly relating to divinity, in three parts. The three parts were printed together as *Petri Berchorii opera omnia* (an incorrect title, for he wrote much besides).

A very popular small encyclopaedia, *Margarita philosophica* (1496), in 12 books, was written by Georg Reisch, a German, prior of the Carthusians of Freiburg, and confessor of the emperor Maximilian I. Books 1–7 treat of the seven liberal arts; 8, 9, principles and origin of natural things; 10, 11, the soul, vegetative, sensitive and intellectual; 12, moral philosophy.

Raphael Maffei (1451–1522), called Volaterranus, being a native of Volterra, wrote *Commentarii Urbani* (1506), so called because written at Rome. This encyclopaedia, printed eight times up to 1603, is remarkable for the great importance given to geography, and also to biography, a subject not included in previous encyclopaedias. The books are not divided into short chapters in the ancient manner, like those of its predecessors. The edition of 1603 contains 814 folio pages.

Giorgio Valla, born about 1430 at Placentia, and therefore called Placentinus, died at Venice in 1499 while lecturing on the immortality of the soul. Aldus published his book, edited by his son Giovanni Pietro Valla, *De expetendis et fugiendis rebus*, an encyclopaedic work containing 49 books and 2,119 chapters.

Antonio Zara, born 1574, made bishop of Petina in Istria 1600, finished in 1614 a work published as *Anatomia ingeniorum et scientiarum*. The first section, on the dignity and excellence of man, considers him in all his bodily and mental aspects. The first membrum describes his structure and his soul, and in the latter part contains the author's preface, the deeds of his ancestors, an account of himself, and the dedication of his book to Ferdinand, archduke of Austria. Four membra treat of the discovery of character by chiromancy, physiognomy, dreams and astrology. The rest of the work treats of 16 "sciences of the imagination," 8 "sciences of intellect," and 12 "sciences of memory." The book, now very rare, is well arranged, with a copious index, and is full of curious learning.

ENCYCLOPAEDIAS AND DICTIONARIES

Alsted's Encyclopaedia.—Johann Heinrich Alsted, born 1588, died 1638, published *Encyclopaedia septem tomis distincta* (1630). It treats of a wide range of subjects, including not only the more important sciences, but paradoxologia, the art of explaining paradoxes; dipnosophistica, the art of philosophizing while feasting; cyclognomica, the art of conversing well *de quovis scibili*, and tabacologia, the nature, use and abuse of tobacco. Alsted's encyclopaedia was received with very great applause, and was highly valued. Lami (*Entretiens*, 1684) thought it almost the only encyclopaedia which did not deserve to be despised. Alsted's learning was very various. He wrote not long before the appearance of encyclopaedias in modern languages superseded his own and other Latin books, and but a short time before the alphabetical arrangement began to prevail over the methodical.

Jean de Magnon, historiographer to the king of France, undertook to write an encyclopaedia in French heroic verse, which was to fill ten volumes of 20,000 lines each, and to render libraries merely a useless ornament. But he did not live to finish it, as he was killed at night by robbers on the Pont Neuf in Paris, in 1662. The part he left was printed as *La Science universelle* (1663)—10 books containing about 11,000 lines. They begin with the nature of God, and end with the history of the fall of man. His verses, say Chaudon and Delandine, are perhaps the most nerveless, incorrect, obscure and flat in French poetry; yet the author had been the friend of Molière, and had acted with him in comedy.

Louis Moréri (born in 1643, died in 1680 at Paris) wrote a dictionary of history, genealogy and biography, *Le Grand Dictionnaire historique, ou le mélange curieux de l'histoire sacrée et profane* (Lyons, 1674), the 20th edition of which was published in 1759. Moréri's dictionary, still very useful, was of great value and importance, although not the first of the kind.

Johann Jacob Hofmann (1635–1706), son of a schoolmaster at Basle, which he is said never to have left, and where he was professor of Greek and History, wrote *Lexicon universale historico-geographico-chronologico-poëtico-philologicum* (1677), a dictionary of history, biography, geography, genealogies of princely families, chronology, mythology and philology. In 1683 he published a continuation in two volumes. From the great extent of his plan, many articles, especially in history, are superficial and faulty.

Etienne Chauvin was born at Nîmes in 1640. He fled to Rotterdam on the revocation of the edict of Nantes, and in 1688 supplied Bayle's place in his lectures on philosophy. In 1695 he was invited to go as professor of philosophy to Berlin, where he became the representative of the Cartesian philosophy. He wrote *Lexicon rationale, sive thesaurus philosophicus ordine alphabetico digestus* (1692). An improved and enlarged edition was printed as *Lexicon philosophicum secundis curis* in 1713. This great work may be considered as a dictionary of the Cartesian philosophy.

Dictionaries of Arts and Sciences.—The great dictionary of French, begun by the French Academy on Feb. 7, 1639, excluded all words especially belonging to science and the arts. But the success of the rival dictionary of Furetière, which, as its title-page, as well as that of the *Essais* published in 1684, conspicuously announced, professed to give "les termes de toutes les Sciences et des Arts," induced Thomas Corneille, a member of the Academy, to compile *Le Dictionnaire des arts et des sciences*, which the Academy published with the first edition of their dictionary (1694) as a supplement in two volumes. A long series of dictionaries of arts and sciences have followed Corneille in placing in their titles the arts before the sciences, which he probably did merely in order to differ from Furetière.

Pierre Bayle (1647–1706) wrote a very important and valuable work, *Dictionnaire historique et critique* (Rotterdam, 1697). His design was to make a dictionary of the errors and omissions of Moréri and others, but he was much embarrassed by the numerous editions and supplements of Moréri. The fourth edition (4 vols., Rotterdam, 1720) was much enlarged from his manuscripts,

and was edited by Prosper Marchand. It contains 3,132 pages besides tables, etc. It was translated into English from the second edition in 1709. Prosper Marchand, editor of the fourth edition, left at his death on Jan. 14, 1756, materials for a supplementary *Dictionnaire historique* (La Haye, 1758). It had occupied his leisure moments for 40 years. Much of his work was written on small scraps of paper, sometimes 20 in half a page and no larger than a nail, in such small characters that not only the editor but the printer had to use powerful magnifiers. Bayle's dictionary is still a work of great importance and value.

Vincenzo Maria Coronelli, a Franciscan friar, who was born in Venice about 1650, made cosmographer to the republic in 1685, and became general of his order in 1702, began in 1701 to publish a general alphabetical encyclopaedia, written in Italian, at which he had been working for 30 years, *Biblioteca universale sacro-profana.* It was to explain more than 300,000 words, to include history and biography as well as all other subjects, and to extend to 45 volumes folio. But seven volumes only were published (Venice, 1701–06), A to Caque. This work is remarkable for the extent and completeness of its plan, and for being the first great alphabetical encyclopaedia, as well as for being written in a modern language, but it was hastily written and very incorrect. Never, perhaps, says Tiraboschi, was there so quick a writer; he composed a folio volume as easily as others would a page.

The First Alphabetical Encyclopaedias in English.—The first alphabetical encyclopaedia written in English was the work of a London clergyman, John Harris (born about 1667, elected first secretary of the Royal Society in 1709, died 1719), *Lexicon technicum, or an universal English Dictionary of Arts and Sciences* (1704). As in many subsequent English encyclopaedias the pages are not numbered. It professes not merely to explain the terms used in the arts and sciences, but the arts and sciences themselves. The author omits theology, antiquity, biography and poetry. This volume was reprinted in 1708. A second volume of 1,419 pages appeared in 1710, with a list of about 1,300 subscribers. A great part of it consisted of mathematical and astronomical tables, as he intended his work to serve as a small mathematical library. He was allowed by Sir Isaac Newton to print his treatise on acids. The mathematical and physical part is considered very able. He often mentions his authorities, and gives lists of books on particular subjects, as botany and chronology. His dictionary was long very popular. The fifth edition was published in 1736.

Johann Hübner, rector of the Johanneum in Hamburg, born 1668, wrote prefaces to two dictionaries written in German, which bore his name, and were long popular. The first was *Reales Staats Zeitungs- und Conversations-Lexicon* (Leipzig 1704); the second, published as a supplement, was *Curieuses und reales Natur-Kunst- Berg- Gewerb- und Handlungs-Lexicon* (Leipzig, 1712), frequently reprinted to 1792. The first relates to the political state of the world, treating of religion, orders, States, rivers, towns, castles, mountains, genealogy, war, ships; the second to nature, science, art and commerce. They were the work of many authors, among whom Paul Jacob Marpurger, a celebrated and voluminous writer on trade and commerce, was an extensive contributor.

Johann Theodor Jablonski, who was born at Danzig in 1654, and was appointed secretary to the newly founded Prussian Academy in 1700, when he went to Berlin, published *Allgemeines Lexicon der Künste und Wissenschaften* (Leipzig, 1721), a short but excellent encyclopaedia still valued in Germany. It does not include theology, history, geography, biography and genealogy. He not only names his authorities, but gives a list of their works.

Ephraim Chambers (*q.v.*) published his *Cyclopaedia; or an Universal Dictionary of Art and Sciences, containing an Explication of the Terms and an Account of the Things Signified thereby in the several Arts, Liberal and Mechanical, and the several Sciences, Human and Divine,* in 1728 (2 vols.). Chambers endeavoured to connect the scattered articles relating to each subject by a system of references, and to consider "the several matters, not only in themselves, but relatively, or as they respect each other; both to treat them as so many wholes and as so many parts of some greater whole." Under each article he refers to the subject to which it belongs, and also to its subordinate parts; thus Copyhold has a reference to Tenure, of which it is a particular kind, and other references to Rolls, Custom, Manor, Fine, Charterland and Freehold. His work, he says, is a collection, not the produce of one man's wit, for that would go but a little way, but of the whole commonwealth of learning. To the subjects given by Harris he adds theology, metaphysics, ethics, politics, logic, grammar, rhetoric and poetry, but excludes history, biography, genealogy, geography and chronology, except their technical parts. A second edition appeared in 1738. A few articles were added and some others enlarged, but he was prevented from doing more because "the booksellers were alarmed with a bill in parliament containing a clause to oblige the publishers of all improved editions of books to print their improvements separately." The bill after passing the Commons was unexpectedly thrown out by the Lords; but fearing that it might be revived, the booksellers thought it best to retreat though more than 20 sheets had been printed. An Italian translation (Venice, 1748–49), was the first complete Italian encyclopaedia. When Chambers was in France in 1739 he rejected very favourable proposals to publish an edition there dedicated to Louis XV. His work was judiciously, honestly and carefully done, and long maintained its popularity. At his death, on May 15, 1740, he had collected and arranged materials for seven new volumes. The *Supplement,* edited hastily by Dr. (later Sir) John Hill, was published in 1753. As Hill was a botanist, the botanical part, which had been very defective in the *Cyclopaedia,* was the best. Abraham Rees (1743–1825), a Nonconformist minister, published a revised and enlarged edition, "with the supplement and modern improvements incorporated in one alphabet" (1778–88). It was published in 418 numbers at 6d. each. Rees said that he added more than 4,400 new articles.

Zedler's Universal Lexicon.—One of the largest and most comprehensive encyclopaedias was undertaken and in a great measure completed by Johann Heinrich Zedler, a bookseller of Leipzig, who was born at Breslau in 1706, made a Prussian commerzienrath in 1731, and died at Leipzig in 1760—*Grosses vollständiges Universal Lexicon Aller Wissenschaften und Künste welche bisher durch menschlichen Verstand und Witz erfunden und verbessert worden* (64 vols., Halle and Leipzig, 1732–50); and *Nöthige Supplemente* (*ib.,* 1751–54, vols. i. to iv., A. to Caq, 3,016 pages). Nine editors were employed, and the whole of each subject was entrusted to the same person, that all its parts might be uniformly treated. The work was published by subscription. Johann Heinrich Wolff, an eminent merchant and shopkeeper in Leipzig, came to Zedler's assistance by advancing the funds for expenses and becoming answerable for the subscriptions, and spared no cost that the work might be complete. Zedler very truly says that his *Universal Lexicon* was a work such as no time and no nation could show, and both in its plan and execution it is much more comprehensive and complete than any previous encyclopaedia. Its plan embraces not only history, geography and biography, but also genealogy, topography, and from vol. xviii., published in 1738, lives of illustrious living persons. Zedler enquires why death alone should make a deserving man capable of having his services and worthy deeds made known to the world in print. Cross references generally give not only the article referred to, but also the volume and column, and, when necessary, such brief information as may distinguish the word referred to from others similar but of different meaning. Lists of authorities, often long, exact and valuable, are frequently appended to the articles. This work, which is well and carefully compiled, and very trustworthy, is still a most valuable book of reference on many subjects, especially topography, genealogy and biography. The genealogies and family histories are excellent, and many particulars are given of the lives and works of authors not easily found elsewhere.

A work on a new plan was published by Dennis de Coetlogon, a Frenchman naturalized in England, who styled himself "Knight of St. Lazare, M.D., and member of the Royal Academy of Angers"—*An Universal History of Arts and Sciences* (2 vols., 1745). He "endeavours to render each treatise as complete as possible, avoiding above all things needless repetitions, and never puzzling the reader with the least reference." The subject matter

is sometimes curious. The author says that his work is the only one of the kind, and that he wrote out with his own hand every line, even the index. But notwithstanding the novelty of his plan, his work does not seem ever to have been popular.

Gianfrancesco Pivati (1689–1764), secretary of the Academy of Sciences at Venice, who had published in 1744 a 4to volume containing a *Dizionario universale*, wrote *Nuovo dizionario scientifico e curioso sacroprofano* (Venice, 1746–51, 10 vols., 597 plates). It is a general encyclopaedia, including geography, but not history or biography. It is remarkable for the number of its plates, which are engraved on copper.

The French Encyclopaedists.—One of the greatest and most remarkable literary enterprises of the 18th century, the famous French *Encyclopédie,* originated in a French translation of Ephraim Chambers's *Cyclopaedia,* begun in 1743 and finished in 1745 by John Mills, an Englishman resident in France, assisted by Gottfried Sellius. They applied to Lebreton, the king's printer, to publish the work, to fulfil the formalities required by French law, with which, as foreigners, they were not acquainted, and to solicit a royal privilege. This he did for them, but only in his own name. Mills complained so loudly and bitterly of this deception that Lebreton had to acknowledge formally that the privilege belonged *en toute propriété* to John Mills. Mills, however, again became the victim of trickery and was ultimately despoiled of the work he had both planned and executed, and had to return to England. Jean Paul de Gua de Malves, professor of philosophy in the college of France, was then engaged as editor merely to correct errors and add new discoveries. But he proposed a thorough revision, and obtained the assistance of many learned men and artists, among whom Desessarts names Louis, Condillac, d'Alembert and Diderot. But the publishers did not think his reputation high enough to ensure success, withheld their confidence, and often opposed his plans as too expensive. De Gua resigned the editorship. The publishers, who had already made heavy advances, offered it to Diderot, who was probably recommended to them by his very well received *Dictionnaire universel de médicine* (1746–48), a translation, made with the assistance of Eidous and Toussaint, of the celebrated work of Dr. Robert James (inventor of the fever powders), *A Medicinal Dictionary.* The proposed work was to have been similar in character.

De Gua's papers were handed over to Diderot in great confusion. He soon persuaded the publishers to undertake a far more original and comprehensive work. His friend d'Alembert undertook to edit the mathematics. Other subjects were allotted to 21 contributors, each of whom received the articles on his subject in Mills's translation to serve as a basis for his work. But they were in most cases so badly composed and translated, so full of errors and omissions, that they were not used. The contributions were to be finished in three months, but none was ready in time, except Music by Rousseau, which he admits was hastily and badly done. Diderot was imprisoned at Vincennes, on July 29, 1749, for his *Lettre sur les aveugles.* He was closely confined for 28 days, and was then for three months and ten days a prisoner on parole in the castle. This did not stop the printing, though it caused delay. The prospectus by Diderot appeared in Nov. 1750. The work was to form 8 vols., with at least 600 plates. The first volume was published in July 1751; the second appeared in Jan. 1752. An *arrêt* of the council suppressed both volumes as injurious to the king's authority and to religion. Malesherbes, director-general of the Librairie, stopped the issue of vol. ii. on Feb. 9, and on the 21st went with a *lettre de cachet* to Lebreton's to seize the plates and the mss., but did not find even those of vol. iii., as they had been taken to his own house by Diderot and one of the publishers. The Jesuits tried to continue the work, but in vain. It was less easy, says Grimm, than to ruin philosophers. The Government had to request the editors to resume the work as one honourable to the nation. Vol. iii., rather improved by the delay, appeared in Oct. 1753; and vol. vii., completing G, in Nov. 1757. The clamours against the work soon recommenced. D'Alembert retired in Jan. 1758, weary of sermons, satires and intolerant and absurd censors. The parlement of Paris, by an *arrêt* of Jan. 23, 1759, stopped the sale and distribution of the *Encyclopédie* and other books; and by an *arrêt* of Feb. 6, ordered them all to be burnt, but referred the *Encyclopédie* for examination to a commission of nine. A *arrêt du conseil* (March 7) revoked the privilege of 1746, and stopped the printing. Vol. viii. was then in the press. Malesherbes warned Diderot that he would have his papers seized next day; and when Diderot said he could not make a selection, or find a place of safety at such short notice, Malesherbes said, "Send them to me, they will not look for them there." Malesherbes, Choiseul and Mme. de Pompadour protected the work. Diderot obtained private permission to go on printing, but with a strict charge not to publish any part until the whole was finished. The Jesuits were condemned by the parlement of Paris in 1762, and by the king in Nov. 1764. Vol. i. of plates appeared in 1762, and vol. viii. to xvii., ten volumes of text, 9,408 pages, completing the work, with the 4th volume of plates in 1765, when there were 4,250 subscribers. The work was secretly distributed in Paris and Versailles. The general assembly of the clergy, on June 20, 1765, approved articles in which it was condemned, and on Sept. 27 adopted a *mémoire* to be presented to the king. They were forbidden to publish their acts which favoured the Jesuits, but Lebreton was required to give a list of his subscribers, and was put into the Bastille for eight days in 1766. A royal order was sent to the subscribers to deliver their copies to the lieutenant of police. Voltaire in 1774 relates that, at a *petit souper* of the king at Trianon, there was a debate on the composition of gunpowder. Mme. de Pompadour said she did not know how her rouge or her silk stockings were made. The duc de la Vallière regretted that the king had confiscated their encyclopaedias, which could decide everything. The king said he had been told that the work was most dangerous, but as he wished to judge for himself, he sent for a copy. Three servants with difficulty brought in the 21 volumes. The company found everything they looked for, and the king allowed the confiscated copies to be returned. Lebreton, who had the largest printing office in Paris, employed 50 workmen in printing the last ten volumes. He had the articles set in type exactly as the authors sent them in, and when Diderot had corrected the last proof of each sheet, he and his foreman, hastily, secretly and by night, unknown to his partners in the work, cut out whatever seemed to them daring, or likely to give offence, mutilated most of the best articles without any regard to the consecutiveness of what was left, and burnt the manuscript. The printing of the work was nearly finished when Diderot, having to consult one of his great philosophical articles in the letter S, found it entirely mutilated. He was confounded, says Grimm, at discovering the atrocity of the printer; all the best articles were in the same confusion. This discovery put him into a state of frenzy and despair from rage and grief. Diderot at first refused to correct the remaining proofs, or to do more than write the explanations of the plates. He required, according to Mme. de Vandeul, that a copy (now at Leningrad with his library) should be printed with columns in which all was restored. Diderot's articles were on very many subjects, but principally on grammar, history, morality, philosophy, literature and metaphysics. As a contributor, his special department of the work was philosophy, and arts and trades. He passed whole days in workshops, and began by examining a machine carefully, then he had it taken to pieces and put together again, then he watched it at work, and lastly worked it himself. He thus learned to use such complicated machines as the stocking and cut velvet looms. He at first received 1,200 livres a year as editor, but afterwards 2,500 livres a volume, besides a final sum of 20,000 livres. All the publishers made large fortunes; their expenses amounted to 1,158,000 livres and their profits to 2,162,000.

In the *Encyclopédie,* as in Ephraim Chambers's *Cyclopaedia,* history and biography were excluded, except incidentally; thus Aristotle's life is given in the article Aristotélisme. The science to which an article belongs is generally named at the beginning of it, references are given to other articles, and the authors' names are marked by initials, of which lists are given in the earlier volumes, but sometimes their names are subscribed in full. Articles by Diderot have no mark, and those inserted by him as editor have an asterisk prefixed. Among the contributors were Voltaire,

Euler, Marmontel, Montesquieu, D'Anville, D'Holbach and Turgot, the leader of the new school of economists which made its first appearance in the pages of the *Encyclopédie*. No encyclopaedia perhaps has been of such political importance, or has occupied so conspicuous a place in the civil and literary history of its century. It sought not only to give information, but to guide opinion. It was, as Rosenkranz says (*Diderot*, i. 157), theistic and heretical. It was opposed to the church, then all-powerful in France, and it treated dogma historically. It was, as Desnoiresterres says (*Voltaire*, v. 164), a war machine; as it progressed, its attacks both on the church and the still more despotic Government, as well as on Christianity itself, became bolder and more undisguised, and it was met by opposition and persecution unparalleled in the history of encyclopaedias. Its execution is very unequal, and its articles of very different value. It was not constructed on a regular plan, or subjected to sufficient supervision; articles were sent in by the contributors, and not seen by the editors until they were in type. In each subject there are some excellent articles, but others are very inferior, and references are often given to articles which do not exist. The style is too generally loose, digressive and inexact; dates are seldom given; and discursiveness, verbosity and dogmatism are frequent faults. Voltaire was constantly demanding truth, brevity and method, and said it was built half of marble and half of wood. D'Alembert compared it to a harlequin's coat, in which there is some good stuff but too many rags. Diderot was dissatisfied with it as a whole; much of it was compiled in haste; and carelessly written articles and incompetent contributors were admitted for want of money to pay good writers. Zedler's *Universal Lexicon* is on the whole much more useful for reference than its far more brilliant successor. The books attacking and defending the *Encyclopédie* are very many. No original work of the 18th century, says Lanfrey, has been more deprecated, ridiculed and calumniated. It has been called chaos, nothingness, the Tower of Babel, a work of disorder and destruction, the gospel of Satan and even the ruins of Palmyra.

THE ENCYCLOPÆDIA BRITANNICA

The *Encyclopædia Britannica or Dictionary of Arts and Sciences*, "by a society of gentlemen in Scotland, printed in Edinburgh for A. Bell and C. Macfarquhar, and sold by Colin Macfarquhar at his printing office in Nicolson street," was completed in 1771 in 3 vol. 4to, containing 2,670 pages, and 160 copperplates engraved by Andrew Bell. It was published in numbers, of which the first two were issued in Dec. 1768, "price 6d. each, or 8d. on a finer paper," and was to be completed in 100 weekly numbers. It was compiled, as the title-page says, on a new plan. The different sciences and arts were "digested into distinct treatises or systems," of which there are 45 with cross headings, *i.e.*, titles printed across the page, and about 30 other articles more than three pages long. The longest are "Anatomy," 166 pages, and "Surgery," 238 pages. "The various technical terms, etc., are explained as they occur in the order of the alphabet." "Instead of dismembering the sciences, by attempting to treat them intelligibly under a multitude of technical terms, they have digested the principles of every science in the form of systems or distinct treatises, and explained the terms as they occur in the order of the alphabet, with references to the sciences to which they belong." This plan, as the compilers say, differs from that of all the previous dictionaries of arts and sciences. Its merit and novelty consist in the combination of De Coetlogon's plan with that in common use—on the one hand keeping important subjects together, and on the other facilitating reference by numerous separate articles. It is doubtful to whom the credit of this plan is due. The editor, William Smellie, a printer (born in 1740, died on June 24, 1795), afterwards secretary and superintendent of natural history to the Society of Scottish Antiquaries, is said by his biographer to have devised the plan and written or compiled all the chief articles. Archibald Constable, who was interested in the work from 1788, and was afterwards intimately acquainted with Bell, says Colin Macfarquhar was the actual projector of the *Encyclopædia*, and the editor of the first two editions, while Smellie was merely "a contributor for hire." Dr. Gleig, in his preface to the third edition, says: "The idea had been conceived by him (Colin Macfarquhar) and his friend, Mr. Andrew Bell, engraver." Macfarquhar, according to Constable, was a person of excellent taste and very general knowledge, though at starting he had little or no capital, and was obliged to associate Bell, then the principal engraver in Edinburgh, as a partner in his undertaking.

The second edition was begun in 1776, and was published in numbers, of which the first was issued on June 21, 1777, and the last, No. 181, on Sept. 18, 1784, forming 10 vols, 4to, dated 1778 to 1783, and containing 8,595 pages and 340 plates. The pagination is continuous, ending with page 9,200, but 295 pages are inserted in various places, and page 7,099 is followed by 8,000. The number and length of the articles were much increased, 72 have cross headings, and more than 150 others may be classed as long articles. At the end is an appendix ("Abatement" to "Wood") of 200 pages, containing, under the heading Botanical Table, a list of the 931 genera included in the 58 natural orders of Linnaeus, and followed by a list of 526 books, said to have been the principal authorities used. All the maps are placed together under the article "Geography" (195 pages). Most of the long articles have numbered marginal titles; "Scotland," 84 pages, has 837. "Medicine," 309 pages, and "Pharmacy" have each an index. The plan of the work was enlarged by the addition of history and biography, which encyclopaedias in general had long omitted. Smellie was applied to by Bell to edit the second edition, and to take a share of one-third in the work; but he refused on the ground that the introduction of a system of general biography was inconsistent with the character of a dictionary of arts and sciences. James Tytler, M.A., seems to have been selected as the next most eligible compiler. Tytler (outlawed by the High Court of Justiciary in 1793, buried at Salem in Massachusetts in 1804, aged 58) "wrote," says Watt, "many of the scientific treatises and histories, and almost all the minor articles."

The Third Edition.—After about a year's preparation, the third edition was announced in 1787; the first number was published early in 1788, and the first volume in Oct. 1788. There were to be 300 weekly numbers, price 1s. each, forming 30 parts at 10s. 6d. each, and 15 volumes, with 360 plates. It was completed in 1797 in 18 vols. 4to, containing 14,579 pages and 542 plates. Among the multifarious articles represented in the frontispiece, which was required by the traditional fashion of the period, is a balloon. The maps are, as in subsequent editions, distributed among the articles relating to the respective countries. It was edited by Colin Macfarquhar as far as the article "Mysteries," when he died, in 1793 in his 48th year, "worn out," says Constable, "by fatigue and anxiety of mind." His children's trustees and Andrew Bell requested George Gleig of Stirling (consecrated on Oct. 30, 1808, assistant and successor to the bishop of Brechin), who had written about 12 articles, to edit the rest of the work. According to Kerr (*Smellie's Life*, i. 364–365), 10,000 copies were printed, and the profit to the proprietors was £42,000, besides the payments for their respective work as tradesmen in the conduct of the publication—Bell as engraver of all the plates, and Macfarquhar as sole printer. According to Constable, the impression was begun at 5,000 copies, and concluded with a sale of 13,000. James Hunter, "an active bookseller of no character," who had a shop in Middle Row, Holborn, sold the book to the trade, and on his failure Thomson Bonar, a wine merchant, who had married Bell's daughter, became the seller of the book. He quarrelled with his father-in-law, who would not see him during the ten years before his death. When the edition was completed, the copyright and remaining books were sold in order to wind up the concern, and "the whole was purchased by Bell, who gave £13 a copy, sold all the complete copies to the trade, printed up the odd volumes, and thus kept the work in the market for several years."

SUPPLEMENTS AND OTHER EDITIONS

The supplement of the third edition, printed for Thomson Bonar, and edited by Gleig, was published in 1801 in 2 vols., containing 1,624 pages and 50 copperplates engraved by D. Lizars. In the dedication to the king, dated Stirling, Dec. 10, 1800, Dr. Gleig says: "The French *Encyclopédie* had been accused, and

justly accused, of having disseminated far and wide the seeds of anarchy and atheism. If the *Encyclopædia Britannica* shall in any degree counteract the tendency of that pestiferous work, even these two volumes will not be wholly unworthy of your Majesty's attention." Dr. Thomas Thomson wrote "Chemistry," "Mineralogy" and other articles, in which the use of symbols was for the first time introduced into chemistry; and these articles formed the first outline of his *System of Chemistry*.

The fourth edition, printed for Andrew Bell, was begun in 1800 or 1801, and finished in 1810 in 20 vols. 4to, containing 16,033 pages, with 581 plates engraved by Bell. No articles were reprinted from the supplement, as Bell had not the copyright. Prof. Wallace's articles on mathematics were much valued, and raised the scientific character of the work. Dr. Thomas Thomson declined the editorship, and recommended Dr. James Millar, afterwards editor of the *Encyclopaedia Edinensis*. He was fond of natural history and a good chemist, but, according to Constable, slow and dilatory and not well qualified. The edition began with 1,250 copies and concluded at 4,000, of which two-thirds passed through the hands of Constable's firm. Early in 1804 Andrew Bell had offered Constable and his partner Hunter the copyright of the work, printing materials, etc., and all that was then printed of the fourth edition, for £20,000. This offer was in agitation in March 1804, when the two partners were in London. On May 5, 1804, after Lord Jeffrey's arrival in Edinburgh, as he relates to Francis Horner, they entrusted him with a design, on which he found that most of his friends had embarked with great eagerness, "for publishing an entire new encyclopaedia upon an improved plan. . . . W. Scott has embraced it with great affection. . . . The authors are to be paid at least as well as reviewers, and are to retain the copyright of their articles for separate publication if they think proper." It was then, perhaps, that Constable gave £100 to Bonar for the copyright of the supplement.

Andrew Bell died in 1809, and a fifth edition was begun immediately after the fourth as a mere reprint. Bell's trustees mismanaged the new edition so badly that, after the issue of five volumes, both the stock and the copyright were sold to Constable who paid between £13,000 and £14,000. Bonar, who lived next door to the printing office, thought he could conduct the book, and had resolved on the purchase. Having a good deal of money, he seemed to Constable a formidable rival, whose alliance was to be secured. After "sundry interviews" it was agreed that Constable should buy the copyright in his own name, and that Bonar should have one-third, and also one-third of the copyright of the supplement, for which he gave £200. Dr. James Millar corrected and revised the last 15 volumes. The edition dated 1817 was published in 20 vols., 16,017 pages, 582 plates, price £36.

Famous Contributors.—Soon after the purchase of the copyright, Constable began to prepare for the publication of a supplement, to be of four or, at the very utmost, five volumes. Dugald Stewart, in a letter to Constable, Nov. 15, 1812, though he declines to engage to execute any of his own suggestions, recommends that four discourses should "stand in front," forming "a general map of the various departments of human knowledge," similar to "the excellent discourse prefixed by D'Alembert to the French *Encyclopédie*," together with historical sketches of the progress since Bacon's time of modern discoveries in metaphysical, moral and political philosophy, in mathematics and physics, in chemistry, and in zoology, botany and mineralogy. He would only promise to undertake the general map and the first historical sketch, if his health and other engagements permitted. For the second he recommended Playfair, for chemistry Sir Humphry Davy. He received £1,000 for the first part of his dissertation (166 pages), and £700 for the second (257 pages), the right of publication being limited to the Supplement and *Encyclopædia*. Constable next contracted with Prof. Playfair for a dissertation "to be equal in length or not to Stewart's." He at first intended to have two editors, "one for the strictly literary and the other for the scientific department." He applied to Dr. Thomas Brown, who "preferred writing trash of poetry to useful and lucrative employment." At last he fixed on Macvey Napier (born 1777), whom he had known from 1798, and who "had been a hard student, and at college laid a good foundation for his future career, though more perhaps in general information than in what would be, strictly speaking, called scholarship." Napier went to London, and obtained the co-operation of many literary men. The supplement was published in half-volume parts from Dec. 1816 to April 1824. It formed six volumes 4to, containing 4,933 pages, 125 plates, 9 maps, three dissertations and 669 articles, of which a list is given at the end. The first dissertation, on the "progress of metaphysical, ethical and political philosophy," was by Stewart, who completed his plan only in respect to metaphysics. These historical dissertations were admirable and delightful compositions, and important and interesting additions to the *Encyclopædia*; but it is difficult to see why they should form a separate department distinct from the general alphabet. Among the distinguished contributors were James Mill, Ricardo, Malthus, Arago, Biot, Hazlitt and Sir Walter Scott, who, to gratify his generous friend Constable, laid aside *Waverley*, which he was completing for publication, and in April and May 1814 wrote "Chivalry." There were about 160 biographies, chiefly of persons who had died within the preceding 30 years. Signatures, on the plan of the *Encyclopédie*, were annexed to each article, the list forming a triple alphabet, A to XXX, with the full names of the 72 contributors arranged apparently in the order of their first occurrence. At the end of vol. vi. are Addenda and Corrigenda.

The sixth edition, "revised, corrected and improved," appeared in half-volume parts, price 16s. in boards, vol. xx. part ii. completing the work in May 1823. Constable, thinking it not wise to reprint so large a book year after year without correction, in 1820 selected Charles Maclaren (1782–1866), as editor. "His attention was chiefly directed to the historical and geographical articles. He was to keep the press going, and have the whole completed in three years." A new edition in 25 vols. was contemplated, not to be announced till a certain time after the supplement was finished; but Constable's house stopped payment on Jan. 19, 1826, and his copyrights were sold by auction. Those of the *Encyclopædia* were bought by contract, on July 16, 1828, for £6,150, by Thomas Allan, proprietor of the *Caledonian Mercury*, Adam Black, Abram Thomson, bookbinder, and Alexander Wight, banker, who, with the trustee of Constable's estate, had previously begun the seventh edition. Not many years later Black purchased all the shares and became sole proprietor.

The seventh edition, 21 vols. 4to (with an index of 187 pages), containing 17,101 pages and 506 plates, edited by Macvey Napier, assisted by James Browne, LL.D., was begun in 1827, and published from March 1830 to Jan. 1842. It was reset throughout and stereotyped. Mathematical diagrams were printed in the text from woodcuts. The dissertations of Stewart and others and their index of 30 pages, filled vol. i. As they did not include Greek philosophy, "Aristotle," "Plato" and "Socrates" were supplied by Dr. Hampden, afterwards bishop of Hereford. Among the numerous contributors of eminence, mention may be made of Sir David Brewster, Thomas De Quincey, Antonio Panizzi and Robert Stephenson. Zoology was divided into 11 chief articles, "Mammalia," "Ornithology," "Reptilia," "Ichthyology," "Mollusca," "Crustacea," "Arachnides," "Entomology," "Helminthology," "Zoophytes," and "Animalcule"—all by James Wilson.

The eighth edition, 1853–60, 21 vols. (and index of 239 pages, 1861), containing 17,957 pages and 402 plates, with many woodcuts, was edited by Dr. Thomas Steward Traill, professor of medical jurisprudence in Edinburgh university. The dissertations were reprinted, with one on the "Rise, Progress and Corruptions of Christianity" by Archbishop Whately. Lord Macaulay, Charles Kingsley, Robert Chambers, Rev. Charles Merivale, Dr. Hooker, Henry Austin Layard, Baron Bunsen, Sir John Herschel, Professors Owen, William Thomson and Blackie, were some of the many eminent new contributors found among the 344 authors, of whom an alphabetical list is given, with a key to the signatures. This edition was not wholly reset like the seventh, but many long articles were retained almost or entirely intact.

The publication of the ninth edition (A. and C. Black) was commenced in Jan. 1875, under the editorship of Thomas Spencer Baynes until 1880, and subsequently of W. Robertson Smith, and

completed in 1889, 24 vols., with index. This great edition retained a certain amount of the valuable material in the eighth, but was substantially a new work; and it was universally acknowledged to stand in the forefront of the scholarship of its time. Its contributors included the most distinguished men of letters and of science. In 1898 a reprint, sold at about half the original price, and on the plan of payment by instalments, was issued by *The Times* of London; and in 1902, under the joint editorship of Sir Donald Mackenzie Wallace, President Arthur T. Hadley of Yale university, and Hugh Chisholm, 11 supplementary volumes were published, forming, with the 24 vols. of the ninth edition, a tenth edition of 35 volumes. These included a volume of maps, and an elaborate index (vol. 35) of some 600,000 entries.

In May 1903 a start was made with the preparation of the 11th edition, under the general editorship of Hugh Chisholm and a staff of editorial assistants, the whole work of organization being conducted up to Dec. 1909 from *The Times* office. Arrangements were then made by which the copyright and control of the Encyclopædia Britannica passed to Cambridge university, for the publication at the University Press in 1910–11 of the 29 volumes (one being Index) of the 11th edition, a distinctive feature of this issue being the appearance of the whole series of volumes practically at the same time, though much of the material had been prepared some time in advance. The 12th edition, which appeared in 1922, consisted of the 11th edition, with three supplementary volumes, and was published in Great Britain by Encyclopædia Britannica Company Ltd., and in the United States by the Encyclopædia Britannica, Inc. This supplement to the 11th edition was rendered necessary by the convulsion of the World War. Hugh Chisholm was again the editor, while the New York branch of the editorial staff was under Franklin H. Hooper as American editor. It was soon realized, however, that while these three supplementary volumes were of great value as showing the state of the world, politically, geographically and intellectually, in the years immediately following the war, they were written too close to that gigantic struggle and lacked the cooperation of scholars from many of the Continental countries. Not long afterwards, therefore, under the editorship of J. L. Garvin, with Franklin H. Hooper as American editor, a further three-volume supplement, making the 13th edition (1926) was prepared, which gave a new survey of the march of events, the progress of knowledge and the innumerable changes of the world's aspect, thoughts and activities, in the years from 1910 to 1926. Marshal Foch, Lord Cecil, Albert Einstein, Commissar Trotsky, Mme. Curie, Dr. Stresemann, President Masaryk, Elihu Root and Emile Vandervelde were among the contributors whose names gave an international authority to the new volumes. The present edition, the 14th (1929), is again edited by J. L. Garvin, with Franklin H. Hooper as American editor, with the co-operation of over three thousand distinguished contributors from all countries of the world, and is a fresh and full survey of human knowledge in all its departments—a complete rebuilding of the entire work. It is unique in that it was all prepared and published at one time and is therefore a true cross section of the world's knowledge of to-day.

ENCYCLOPÉDIE AND CONVERSATIONS-LEXICONS

Later History of the Encyclopédie.—A new and enlarged edition of the *Encyclopédie* arranged as a system of separate dictionaries, and entitled *Encyclopédie méthodique ou par ordre de matières*, was undertaken by Charles Joseph Panckoucke (1736–98), a publisher of Paris. His privilege was dated June 20, 1780. The articles belonging to different subjects would readily form distinct dictionaries, although, having been constructed for an alphabetical plan, they seemed unsuited for any system wholly methodical. Two copies of the book and its supplement were cut up into articles, which were sorted into subjects. The division adopted was: 1, mathematics; 2, physics; 3, medicine; 4, anatomy and physiology; 5, surgery; and so on through 26 subjects—all forming distinct dictionaries entrusted to different editors. The first object of each editor was to exclude all articles belonging to other subjects, and to take care that there should be no omissions owing to doubts as to which editor should deal with certain words. In some words (such as air, which belonged equally to chemistry, physics and medicine) the methodical arrangement has the unexpected effect of breaking up the single article into several, widely separated. Each dictionary was to have an introduction and a classified table of the principal articles. History and its minor parts, as inscriptions, fables, medals, were to be included. Theology, which was neither complete, exact nor orthodox, was to be by the abbé Bergier, confessor to Monsieur. The whole work was to be completed and connected together by a *Vocabulaire Universel*, 1 vol., with references to all the places where each word occurred, and a very exact history of the *Encyclopédie* and its editions of Panckoucke. The prospectus, issued early in 1782, proposed three editions—84 vols. 8vo, 43 vols. 4to, and 53 vols. 4to, each edition having 7 vols. 4to of 250 to 300 plates each. It was to be issued in livraisons of 2 vols. each, the first to appear in July 1782, and the whole to be finished in 1787. The number of subscribers, 4,072, was so great that the "special-terms" subscription list was closed on April 30. Twenty-five printing offices were employed, and in Nov. 1782 the 1st livraison was issued. A Spanish prospectus was sent out, and obtained 330 Spanish subscribers, with the inquisitor-general at their head. The complaints of the subscribers and his own heavy advances induced Panckoucke, in Nov. 1788, to appeal to the authors to finish the work. Those *en retard* made new contracts, giving their word of honour to put their parts to press in 1788, and to continue them without interruption, so that Panckoucke hoped to finish the whole, including the vocabulary (4 or 5 vols.), in 1792. Whole sciences, as architecture, engineering, hunting, police, games, etc., had been overlooked in the prospectus; a new division was made in 44 parts, to contain 51 dictionaries and about 124 volumes. Permission was obtained on Feb. 27, 1789, to receive subscriptions for the separate dictionaries. Two thousand subscribers were lost by the Revolution. The 50th livraison appeared on July 23, 1792, when all except seven of the dictionaries eventually published had been begun. The publication was continued by Henri Agasse, Panckoucke's son-in-law, from 1794 to 1813, and then by Mme. Agasse, his widow, to 1832, when it was completed in 102 livraisons or 337 parts, forming 166½ vols. of text, and 51 parts containing 6,439 plates. Pharmacy, minerals, education, *ponts et chaussées* had been announced but were not published. The original parts have been so often subdivided or added to that an exact account cannot be given of the work, which contains 88 alphabets, with 83 indexes, and 166 introductions, discourses, etc. The largest dictionaries are medicine, 13 vols., 10,330 pages; zoology, 7 dictionaries, 13,645 pages, 1,206 plates; botany, 12,002 pages, 1,000 plates. The whole is as unmanageable as Migne's *Encyclopédie théologique* (1844–75), 119,059 pages.

The "Conversations-Lexicon."—No work of reference has been more useful and successful, or more frequently copied, imitated and translated, than that known as the *Conversations-Lexikon* of Brockhaus. It was begun as *Conversations-Lexikon mit vorzüglicher Rücksicht auf die gegenwärtigen Zeiten*, Leipzig, 1796 to 1808, 6 vols., 2,762 pages, by Dr. Gotthelf Renatus Löbel (1767–99), who intended to supersede Hübner, and included geography, history, and some biography, besides mythology, philosophy, natural history, etc. Vols. i.–iv. (A to R) appeared 1796 to 1800, vol. v. in 1806. Friedrich Arnold Brockhaus (*q.v.*) bought the work with its copyright in 1808, for 1,800 thalers from the printer, who seems to have got it in payment of his bill. The editor, Christian Wilhelm Franke, by contract dated Nov. 16, was to finish vol. vi. by Dec. 5, and the already projected supplement, 2 vols., by Michaelmas 1809, for 8 thalers a printed sheet. No penalty was specified, but, says his grandson, Brockhaus was to learn that such contracts, whether under penalty or not, are not kept, for the supplement was finished only in 1811. Brockhaus issued a new impression as *Conversations-Lexikon oder kurzgefasstes Handwörterbuch*, etc., 1809–11, and on removing to Altenburg in 1811 began himself to edit the 2nd edition (1812–19, 10 vols.), and, when vol. iv. was published, the 3rd (1814–19). He carried on both editions together until 1817, when he removed to Leipzig, and began the 4th edition as *Allgemeine deutsche Realencyclopädie für die gebildeten Stände: Conversations-Lexikon.* This

title was, in the 14th edition, changed to that of *Brockhaus' Konversations-Lexicon*. The 5th edition was at once begun, and was finished in 18 months. Edition succeeded edition until the appearance of the 14th (1901–03) in 16 vols. with a supplementary volume in 1904. The *Konversations-Lexicon* is intended, not for scientific use, but to promote general mental improvement by giving the results of research and discovery in a simple and popular form without extended details. The articles, often too brief, are excellent and trustworthy, especially on German subjects, give references to the best books, and include biographies of living men.

One of the best German encyclopaedias is that of Meyer, *Neues Konversations-Lexicon*. The first edition, in 37 vols., was published in 1839–52. Later editions, following the arrangement of Brockhaus, are the 4th (1885–90, 17 vols.), the 5th (1894–98, 18 vols.), the 6th (1902–04), and the 7th (1924–28).

The most copious German encyclopaedia is Ersch and Gruber's *Allgemeine Enzyklopädie der Wissenschaften und Künste*, Leipzig. It was designed and begun in 1813 by Prof. Johann Samuel Ersch to satisfy the wants of Germans, only in part supplied by foreign works. It was stopped by the Napoleonic war until 1816, when Prof. Hufeland joined, but he died in 1817 while the specimen part was at press. The editors of the different sections at various times have been some of the best-known men of learning in Germany, including J. G. Gruber, M. H. E. Meier, Hermann Brockhaus, W. Müller and A. G. Hoffmann of Jena. The work is divided into three sections (1) A–G, of which 99 vols. have appeared since 1890, (2) H–N, 43 vols., (3) O–Z, 25 vols. Another valuable German work of an encyclopaedic character is *Handwörterbuch der Staatswissenschaften*, edited by J. Conrad, the last edition of which was published in 1923.

Among British encyclopaedias not previously mentioned, we may refer to Brewster's *Edinburgh Encyclopaedia* (1810–1830), and Wilks's *Encyclopaedia Londinensis* (1810–29). The *Encyclopaedia Metropolitana* (1845, 28 vols.) professed to give sciences and systematic arts entire and in their natural sequence, as shown in the introductory treatise on method by S. T. Coleridge. "The plan was the proposal of the poet Coleridge, and it had at least enough of a poetical character to be eminently unpractical." However defective the plan, the excellence of many of the treatises by Archbishop Whately, Sir John Herschel, Prof. Barlow, Peacock, de Morgan, etc., is undoubted. It is in four divisions, the last only being alphabetical:—I. *Pure Sciences*; II. *Mixed and Applied Sciences*; III. *History and Biography*; IV. *Miscellaneous*, including geography, a dictionary of English (the first form of Richardson's) and descriptive natural history. A re-issue in 38 vols. was announced in 1849.

The very excellent and useful *English Cyclopaedia* (1854–62; supplements, 1869–73), conducted by Charles Knight, based on the *Penny Cyclopaedia* (1833–46, 29 vols.), of which he had the copyright, is in four divisions, all alphabetical, and evidently very unequal as classes:—1, geography; 2, natural history; 3, biography (with 703 lives of living persons); 4, arts and sciences.

Chambers's Encyclopaedia (1860–68, 10 vols.), edited in part by the publishers, but under the charge of Dr. Andrew Findlater as "acting editor" throughout, was founded on the 10th edition of *Brockhaus*. A revised edition appeared in 1874. In the list of 126 contributors were J. H. Burton, Emmanuel Deutsch, Prof. Goldstücker, etc. The articles were generally excellent, more especially on Jewish literature, folk-lore and practical science; but, as in *Brockhaus*, the scope of the work did not allow extended treatment. A further revision took place, and in 1888–92 an entirely new edition was published, in 10 vols., still further new editions being issued in 1895, in 1901 and in 1923–27.

A brief compilation, the *Harmsworth Encyclopaedia* (1905), was published in 40 fortnightly parts (sevenpence each) in England, and as *Nelson's Encyclopaedia* (revised) in 12 vols. (1906) in America. In 1909 *Nelson's Perpetual Loose-Leaf Encyclopaedia* in 12 vols. appeared.

In the United States various encyclopaedias have been published, but without rivaling there in reputation and volume of sales the *Encyclopædia Britannica*.

The *New American Cyclopaedia* (1858–63, 16 vols.) was the work of the editors, George Ripley and Charles Anderson Dana, and 364 contributors, chiefly American. A supplementary work, the *American Annual Cyclopaedia*, a yearly vol. of about 800 pages, was started in 1861, but ceased in 1902. A new edition of the *American Cyclopaedia* (1873–76, 16 vols.) was prepared by the same editors.

Other American encyclopaedias are Alvin J. Johnson's *New Universal Cyclopaedia* (1875–77, 4 vols.), a new edition of which (excellently planned) was published in 8 vols., 1893–95, under the name of *Johnson's Universal Cyclopaedia*; the *Encyclopaedia Americana*, edited by Francis Lieber, which appeared in 1839–47 in 14 vols.; a new work under the same title, published in 1903–04 in 16 vols.; second edition (1906) in 20 vols.; third edition (1910) in 22 vols.; a new and enlarged edition (1918) in 30 vols. (revised 1923), and a later edition (1927–28) in 30 vols.; the *International Cyclopaedia*, partly based on *Chambers's Encyclopaedia* of 1868 and 1880, first appeared in 1884 (revised in 1891, 1894 and 1898). It was superseded in 1902 by the *New International Encyclopaedia* in 17 vols.; second edition (1914–16) in 24 vols.; in 1925 two supplementary vols. appeared.

In Europe a great impetus was given to the compilation of encyclopaedias by the appearance of Brockhaus' *Konversations-Lexicon* (*see* above), which, as a begetter of these works, must rank, in the 19th century, with the *Cyclopaedia* of Ephraim Chambers in the 18th. The following, although in no sense an exhaustive list, may be here mentioned. In France, *Le Grand Dictionnaire universel du XIX^e siècle*, of Pierre Larousse (15 vols., 1866–76), with supplementary volumes in 1877, 1887 and 1890; the *Nouveau Larousse illustré, dictionnaire universel encyclopédique* (7 vols., 1901–04), (this is in no way a re-issue or an abridgment of *Le Grand Dictionnaire* of Pierre Larousse); *La Grande Encyclopédie, inventaire raisonné des sciences, des lettres, et des arts*, in 31 vols. (1886–1903). In Italy we have the *Nuova Enciclopedia Italiana* (14 vols., 1841–51, and in 25 vols., 1875–88); and Senatore Giovanni Gentile has been appointed chief editor of the great post-War undertaking, the *Enciclopedia Italiana Fondazione Treccani*. In Spain, the *Diccionario enciclopedico Hispano-Americano de litteratura, ciencias y artes* was published at Barcelona (25 vols., 1877–99). The Russian encyclopaedia, *Russki Entsiklopedicheski Slovar* (41 vols., 1905, 2 supplementary vols., 1908) was begun in 1890 as a Russian version of Brockhaus' *Konversations-Lexicon*, but became a monumental encyclopaedia to which all the best Russian men of science and letters contributed. A new Russian encyclopaedia *Bolshaya Sovietskaya Entsiklopediya*, under the general editorship of O. V. Schmidt, will, when complete, fill 30 volumes. The names of the contributors occupy 60 pages. Sixty thousand copies are being printed by the publishers, the Communist Academy of the S.S.R. Elaborate encyclopaedias have also appeared in the Polish, Hungarian, Bohemian and Rumanian languages. Of Scandinavian encyclopaedias there have been re-issues of the *Nordësk Conversations-Lexicon*, first published in 1858–63, and of the *Svenskt Conversations-Lexicon*, first published in 1845–51. Among post-War additions of encyclopaedias is *The Illustrated Australian Encyclopaedia*, occupying two volumes and edited by A. W. Jose and H. J. Carter (Sydney, 1925–26).

"ENDEAVOUR," THE, the ship in which Captain Cook made his famous voyages of discovery (1769–70), for the purpose of observing the transit of Venus, and exploring the Southern Pacific. It was a small well-built craft of 370 tons carrying 22 guns, chosen and manned by Cook himself. After making certain astronomical observations on the island of Tahiti, the "Endeavour" progressed through the Pacific. On Oct. 6, 1789 the eastern coast of New Zealand was sighted, followed by the discovery of Australia at a point now identified as Cape Everard.

ENDECOTT, JOHN (*c.* 1588–1665), English colonial governor in America, was born probably at Dorchester, Dorsetshire, England, about 1588. Little is known of him before 1628, when he was one of the six "joint adventurers" who purchased from the Plymouth Company a strip of land about 60 m. wide along the Massachusetts coast and extending westward to the Pacific Ocean. By his associates Endecott was entrusted with the respon-

sibility of leading the first colonists to the region, and with some 60 persons proceeded to Naumkeag (later Salem) where Roger Conant, a seceder from the colony at Plymouth, had begun a settlement two years earlier. He was the local governor of the Massachusetts Bay colony from April 30, 1629, to June 12, 1630, when John Winthrop brought the charter to Salem and became governor of the colony. Endecott continued to take a prominent part in the affairs of the colony, commanding an expedition against the Pequots in 1636. At Salem he was a member of the congregation of Roger Williams, whom he resolutely defended in his trouble with the New England clerical hierarchy. He was deputy-governor in 1641–44, and governor in 1644–45, and served also as commander-in-chief of the militia and as one of the commissioners of the United Colonies of New England, of which in 1658 he was president. On the death of John Winthrop in 1649 he became governor, and by annual re-elections served continuously until his death, with the exception of two years (1650–51 and 1654–55), when he was deputy-governor. Under his authority the colony of Massachusetts Bay made rapid progress, and except in the matter of religious intolerance—he showed great bigotry and harshness, particularly towards the Quakers—his rule was just and praiseworthy. Of him Edward Eggleston says: "A strange mixture of rashness, pious zeal, genial manners, hot temper, and harsh bigotry, his extravagances supply the condiment of humour to a very serious history—it is perhaps the principal debt posterity owes him." He died on March 15, 1665.

See C. M. Endicott, ***Memoirs of John Endecott*** (Salem, 1847), and a "Memoir of John Endecott" in ***Antiquarian Papers*** of the American Antiquarian Society (Worcester, Mass., 1879).

A lineal descendant, WILLIAM CROWNINSHIELD ENDICOTT (1826–1900), graduated at Harvard in 1847, was a justice of the Massachusetts supreme court in 1873–82, and was secretary of War in President Cleveland's cabinet in 1885–89. His daughter, Mary Crowninshield Endicott, was married to the English statesman Joseph Chamberlain in 1888.

ENDEMIC. An adjective signifying that a given infectious disease is constantly present in a population in the sense that a few cases may always be detected on careful search. An endemic disease is liable to assume epidemic proportions (*see* EPIDEMIC) under conditions that are not fully understood. No doubt in endemic diseases, as in the occurrence of epidemics, the existence of chronic carriers of the disease amongst the population (*see* CARRIERS) is of fundamental importance, but the factors of susceptibility and immunity amongst the healthy (*see* IMMUNITY) are equally important and far more difficult to determine. (*See* EPIDEMIOLOGY.)

Subject to the general conditions mentioned above the importance of endemic disease to a community can best be illustrated by a few specific examples.

Diphtheria.—It is certain that in the throats of some apparently normal individuals bacilli are present from time to time, or constantly, which are indistinguishable (except perhaps in some cases or occasions on bacteriological examination) from B. diphtheria. That the individual does not suffer from the clinical disease known as diphtheria depends upon the fact that his active immunity is kept up by reason of his repeated re-inoculation with small doses of the bacteria in his own throat and the toxin they produce. So far the condition concerns the individual alone, but suppose he be a child attending school and that the weather be cold and wet so that the children are confined to close quarters and many of them are afflicted with slight "colds and coughs." Under these conditions the chance of some of these diphtheria bacilli exhaled or expectorated by the "carrier" finding lodgement in the throats of other children is enormously increased. Moreover it is probable under the given conditions that the resistance of these other children to infectious disease will be below normal, and that quite apart from their specific reaction towards B. diphtheria as can be determined by the Schick test. The conditions are eminently favourable for an outbreak (local epidemic) of diphtheria.

Typhoid and Paratyphoid Fevers.—In the case of these diseases the "carrier" side of the problem is similar to that obtaining in diphtheria, but in addition the cultural characteristics of the offending micro-organism play a large part. Not only are the bacteria expelled in enormously larger numbers, but also they contaminate sewage and may, by leakage, contaminate the water supply. Moreover they multiply under saprophytic conditions to a far greater degree than B. diphtheria, for example. Hence the differences between various endemic diseases, though perhaps relatively unimportant so far as concerns the individual, may be of great importance to the community.

Plague.—In this bacterial disease the endemic condition really concerns rats and the fleas they harbour. Actual cases of human plague may be wanting for a time in a community liable to outbreaks and it is only when mortality among the rats causes their parasitic fleas to leave the rodents and attack man that human cases of bubonic or pneumonic plague arise. Hence endemicity in the case of plague is not quite the same phenomenon as in the case of the other diseases we have considered.

Typhus Fever; Malaria.—*Mutatis mutandis*, endemic conditions in these diseases resemble those in bubonic plague. That is to say, the environmental conditions influencing the life-history of the body-louse and the anopheline mosquito, respectively, play dominant parts in the occurrence and dissemination of the two diseases. Nevertheless these factors could not lead to epidemics were it not for the existence of sporadic human cases in the community. And were it not for density of population, need of warmth, conditions of poverty, facility of transport in the case of typhus and for warmth and moisture favouring the multiplication of mosquitoes in the case of malaria, sporadic cases of these two diseases might occur in the community, or even the diseases might be endemic but epidemics would not arise.

Filter-passing Viruses.—In the case of some diseases believed to be due to the action of filter-passing viruses (*q.v.*), *e.g.*, varicella, dengue, distemper, foot-and-mouth disease, some varieties of herpes, there is evidence from the more or less frequent occurrence of epidemics and the outbreak of disease in new-comers into the district that on occasions the respective diseases may be endemic. The conditions underlying these outbreaks of disease are even less well understood than those described, mainly because the nature of the aetiological factor is unknown.

ENDIVE, *Cichorium Endivia*, an annual esculent plant of the family Compositae, commonly reputed to have been introduced into Europe from the East Indies, but, according to some authorities, more probably indigenous to Egypt. It has been cultivated in England for more than 300 years. There are numerous varieties of the endive, forming two groups, the curled or narrow-leaved (var. *crispa*), and the Batavian or broad-leaved (var. *latifolia*), the leaves of which are not curled. The former varieties are those most used for salads, the latter for culinary purposes. The plant requires a light, rich and dry soil, in an unshaded situation. In England sowing for the main crop should begin about the second or third week in June; but for plants required to be used young it may be as early as the latter half of April, and for winter crops up to the middle of August. Transplantation, where early crops are required, has been found inadvisable. The bleaching of endive, to prevent the development of the natural bitter taste of the leaves, is begun about three months after the sowing, and is best effected either by tying the outer leaves around the inner, or by the use of the bleaching-pot. The bleaching may be completed in about ten days in summer, but in winter it takes three or four weeks.

ENDOCRINOLOGY. This science deals with the structure and function of the organs of internal secretion (*endocrine* or *incretory organs*), in health and disease, and has been vigorously developed since 1910. Through observations upon man in private clinics and in university hospitals, and through experimentation upon animals in laboratories, many important new facts have been accumulated concerning these organs, their products (*increta*) and their functions during different periods of the life-cycle of individual organisms. Attempts are being made to co-ordinate these recent discoveries with what was known before, in order that knowledge in this domain may be better systematised and formulated and that the diagnosis and treatment of endocrine

disturbances in man may find securer foundations than the speculative suppositions, often groundless, that have been advanced in a period of expanding research to eke out a store of facts that was felt to be lamentably meagre.

Limitation of the Field.—There is, as yet, no general agreement as to the limits to be set to the field of endocrinology[1]. (The figures throughout the text refer to the bibliography at the end of the article.) Some would include all parts of the body in the category of organs of internal secretion, on the ground that all organs give off chemical substances to the blood and lymph; others would limit membership in the class to a few organs—(*a*) the ductless glands and (*b*) certain glands that, despite the possession of ducts and the production of an external secretion, yield to the blood directly (or through the lymph) materials that are of profound significance either for the growth and differentiation of distant parts or for the automatic regulation of the physiological functions of those parts. In this latter and more restricted sense, the endocrine organs include the thyroid gland, the parathyroid glands, the hypophysis cerebri (or pituitary gland), the suprarenal glands, the islands of Langerhans of the pancreas, and, perhaps, the endocrine portions of the sex glands or gonads. Organs, the products of which serve merely the nutrition of the body or are mere waste substances to be excreted from the body by other organs, would not be so included.

Even with this restriction there is doubt as to just how many organs should be classed as "incretory" and, particularly, as to whether the pineal gland, the posterior lobe of the hypophysis cerebri, the thymus, the liver and the chromaffin tissues should, or should not, be so classed. For practical reasons it would seem better to regard endocrinology, for the present at least, as limited in its field to the structure and functions of the organs of internal secretion in the narrower sense mentioned above rather than to extend its scope so as to include all the organs of the body whose products on entering the blood play any part in chemical regulation. The science which deals with the "hormones" or "chemical messengers" (*cf.* E. H. Starling) in general within the body has been called "hormonology"; endocrinology in the narrower sense would appear to represent an important part or domain of that more comprehensive subject.

Histology and Embryology of the Endocrine Organs.—The gross and microscopic appearances of the principal ductless glands are described elsewhere (*see* DUCTLESS GLANDS). Recent advances in the morphology of these glands have consisted (*a*) of intensive studies of their finer structure by means of more delicate histological technique and (*b*) of more accurate determinations of the mode of origin and the chronological development of these structures in the embryos. Systematic (and quantitative) statistical studies of the normal variations of these organs and their relations to the body as a whole have been undertaken for certain animal species (*e.g.*, the rat). An attempt is also being made to determine precisely the evolutionary processes responsible for the organogenesis and histogenesis of the structures that manufacture the internal secretions, a phase of research regarded as important by biologists and especially by embryologists[2].

Physiology of the Endocrine Organs.—The increta produced by the endocrine organs and delivered to the blood, either directly, or by way of the lymph, appear to be of great importance for the organism as a whole in all phases of the life-cycle (evolution, maturity and involution). During the ***period of evolution***, the progressive phases of the life-cycle (that is, during the development of the individual), these increta play a rôle in the processes of growth, of organ formation and of tissue differentiation[3]. The endocrine substances that participate in the building of the bodily organs and are of significance in the initiation and the continuance of the metamorphoses that occur during growth have been called "harmozones." It is believed that they react with the autochthonous chromosomal substances of the cells of different regions of the body, perhaps in an enzyme-like way, and so form a part of the stimulative and assimilative processes concerned in normal growth and differentiation.

The endocrine organs themselves undergo changes during growth and development; the several organs appear at somewhat different times in the embryo, and vary somewhat in size, in structure, and doubtless, too, in function, at different stages of an organism's unfolding. That the functions of these organs are correlatively connected is certain; and that there are individual, racial and generic variations in these correlations seems very probable. The different varieties of habitus (pyknic, asthenic, athletic) met with inside the limits of normal variation in a single human race, and the skeletal and other somatic peculiarities that characterise the different races of man (*e.g.*, Nordic, Mediterranean, negro, etc.) or of any other animal, say the dog (*e.g.*, bulldog, dachshund, greyhound), though dependent in part on regional chromosomal specificities, are believed to be also in part determined by the differing endocrine "formulae" or "constellations" of their bearers, the hypophysis being dominant, perhaps in one, the thyroid in another, the gonads in a third and so forth. The different combinations and permutations of the incretory influences that are possible are interesting and at the same time appalling to the student of human and animal constitutions[4].

Function of Hormones.—During the period of maturity the hormones from the incretory organs are believed to subserve many important functions, particularly those concerned with automatic adjustments within the organism when disturbances endanger equilibrium[5]. Thus a hormone from the thyroid gland participates in the control of the basal metabolic rate, one from the parathyroid in the control of calcium metabolism, and one from the islands of the pancreas in the control of sugar metabolism. These hormones may act, as is gradually being found out, through the utilisation of various mechanisms; sometimes they exert their influence through affecting other endocrine organs than those by which they are produced, sometimes through the vegetative nervous system and sometimes through direct attack upon the body cells in general. Ignorance here is as yet profound. Slowly, however, facts are emerging, as a result of clinical-pathological studies, of experimental removal of an endocrine organ and observing what follows, of transplantation experiments and of experiments in which substances derived from endocrine organs are fed to, or injected into, healthy or diseased organisms.

Senescence and Rejuvenation.—During the period of involution of an organism, the incretory organs change as do all the other parts of the body. In the ageing process of normal involution, there may be steady general decline through a long series of regressive phases to physiological death. But premature senescence, partial or general, may appear as a result of abnormalities of one or more endocrine organs (gonads, thyroid, etc.), for such abnormalities lead to disturbances of equilibrium of the correlating systems of the body. To a certain extent, "rejuvenescence" can be experimentally achieved by injection or transplantation of certain endocrine tissues (*see* REJUVENATION). It is possible that the appearance of certain malignant growths may come to be correlated with changes in the incretory glands, for in man, alterations in the thymus, thyroid, hypophysis and suprarenals have been found in association with neoplastic growths and, in experimental animals, definite influences of incretory conditions upon the "taking" and growth of neoplastic grafts, have been demonstrated[6]. Adenocarcinomata, for example, are transplantable to certain normal mice but not to castrates of the same species, though if a young testis be also grafted into the castrate, the neoplastic graft can then be made to grow.

Isolation of Chemical Substances.—Physiological chemists have made progress in isolating various potent chemical substances from the organs of internal secretion. Among the more important of these may be mentioned ***epinephrin*** (or *adrenalin*) from chromaffin tissues, ***thyroxin*** from the thyroid gland, *pituitrin* and *antuitrin* from the hypophysis cerebri, *lutein* from corpora lutea of the ovary and insulin (*q.v.*) from the islets of the pancreas. Recently, from the parathyroid glands has been extracted a *parathyroid hormone* that will prevent or control tetany due to parathyroid insufficiency and will regulate the level of the calcium content of the blood; from pituitrin has been isolated an active principle of great potency that will in extremely dilute solutions

cause contraction of uterine muscle; and from ovarian follicular fluid has been separated a hormone that will, on injection, induce a sexually mature condition in immature females[7].

Clinical Endocrinology.—Knowledge of clinical syndromes due to disorders of the endocrine organs has also made rapid strides since 1910, and the symptomatology of the endocrine disorders has been extended and made more precise. Thus the principal endocrine disturbances manifested as Graves' disease, myxoedema, tetany, acromegaly, adiposogenital dystrophy, eunuchism and eunuchoidism, Addison's disease, suprarenal virilism and hirsutism and diabetes mellitus are now far better understood than ever before. There has been a tendency, however, to attempt to push the clinical applications of the scientific advances in endocrinology further than is warranted, and much confusion has arisen both in the profession and among laymen because of failure to distinguish between mere speculations and well-established facts[8]. Fortunately, warnings have been sounded, and more careful workers emphasise the necessity of a more rigidly critical approach to the solution of clinical endocrine problems. This is particularly true of endocrine therapy, which has recently almost run riot. The wishful thinking of unskilled practitioners and their uncontrolled impulses therapeutically to act by administering endocrine products singly and in the form of divers "polyglandular formulae" bade fair, for a time, to become scandalous, aided and abetted as such ill-founded therapy was by ignorant or unscrupulous vendors of endocrine products. Organotherapy and hormonotherapy have scored genuine triumphs; it is unfortunate that their reputation should be sullied by uncritical extravagances[9]. The effects of thyroid extract or thyroxin in myxoedema, of iodine in the prevention of colloid goitre (*q.v.*), of surgical removal of part of the thyroid gland in exophthalmic goitre and of insulin (*q.v.*) in diabetes (*q.v.*) are brilliant examples of therapeutic successes in endocrine domains. The utilisation of certain hormones for their pharmacodynamic effects in disorders not primarily of endocrine origin is proving profitable; the control of paroxysms of bronchial asthma by injections of epinephrin and the restriction of water-excretion through the kidneys in diabetes insipidus by injections of pituitrin, and the use of pituitrin in obstetrics and surgery, of adrenalin in local anaesthesia and of lutein in ovarian dysfunction are notable examples. Organotherapy and hormonotherapy undoubtedly have an important future, but genuine success in these fields can be achieved only by thoughtful, painstaking, rigidly controlled work; progress is only too likely to be retarded and science to be discredited by the rash enthusiast and the credulous ignoramus.

In the United States the Association for the study of Internal Secretions and its journal, *Endocrinology*, are doing much to foster the development of endocrine research.

ENDOCRINOLOGY IN ANIMALS

Since the term "internal secretion" has been used by some authors so indefinitely as to cover the whole realm of chemical exchange in the animal body, it is necessary for the purpose of this definition to restrict it to the production of substances which are liberated into the body fluids by the specific activity of particular structures, and may thus evoke responses in more remote parts. In practically all familiar animals, visible manifestations of activity involve a receptive surface on which the stimulus operates, *e.g.*, *retina* a structure specialized for the performance of the appropriate response (*e.g.*, muscle or gland), and intervening between these two a mechanism of co-ordination. Co-ordination in animals is of two kinds. Cellular animals in general possess tissues endowed with special powers for the conduction of disturbances from the receptive surface to the seat of response. Such tissues constitute the nervous system. But in animals possessing a circulatory system, the latter also provides an avenue through which, not only the chemical equilibrium of the body, but the active responses of the organism, too, can be regulated. Thus, in addition to nervous, there is chemical or endocrine co-ordination. Knowledge of endocrine co-ordination at present is wholly confined to vertebrate species. This is partly because the study of endocrinology has centred round the attempt to define the role of certain organs of an apparently secretory structure, though lacking any connection by duct with the exterior, with the alimentary tract, or with the cavities of the reproductive and excretory organs. The chief of these so-called ductless glands is the *pituitary*, which lies attached to the floor of the brain; the *adrenals*, which lie in close propinquity to the kidneys; the *thyroid* in the ventral aspect of the pharyngeal region; and finally certain masses of cells amid the enzyme-secreting tubules of the pancreas, named *islets of Langerhans* after their discoverer. The islets of Langerhans in certain bony fishes are separate glandular structures unconnected with the pancreas.

The pituitary and adrenal glands are microscopically complex structures. The former consists of three distinct glandular portions with different histological characteristics, the anterior lobe, the *pars tuberalis*, and the *pars intermedia*—the last two, together with a mass of nervous tissue developed from the floor of the embryonic brain, constituting the posterior lobe. The adrenals of land vertebrates consist of two kinds of cells. One type, which forms the core of the gland in mammals, is distinguished by its very specific reaction to chromium compounds, hence called the *chromaphil* or *chromaffine* tissue. The chromaphil tissue of fishes is diffuse. The tissue corresponding to the cortical portion of the mammalian adrenal is an entirely separate entity (interrenal body) in the cartilaginous fishes. The thyroid in all vertebrates, including the lampreys and hagfishes, has a very definite and characteristic microscopic structure, consisting of vesicles of epithelial cells surrounding a jellyish mass (colloid).

In the closing years of the 19th century Oliver and Schafer showed that watery extracts of the adrenal (chromaphil portion) and pituitary (posterior lobe) glands have highly specific and potent effects on the circulatory system of the mammal. Murray demonstrated the efficacy of administration of sheep's thyroids in connection with clinical manifestations (*myxoedema* and *cretin-*

ism) associated with atrophy or under-development of the thyroid gland. But it was not till 1902 that the conception of chemical co-ordination became clarified through the work of Bayliss and Starling, who first clearly demonstrated the reality of internal secretion as a means of regulating active responses in the normal animal. It had been known, previous to their researches, that by the introduction of acid alone into the intestine, intermittent activity of the pancreas, which normally occurs in response to the passage of acid food into the former, could be brought into play, even after all the nervous connections of the gut had been severed. Bayliss and Starling showed that an acid concoction of the mucous membrane of the intestine will, if injected into the blood stream, evoke an immediate flow of pancreatic juice. These and other experiments showed that liberation, by the acid food, of a soluble product, whose precursor is present in the enteric mucosa, provides the signal for pancreatic secretion. Diffusing into the blood stream, this product, called by its discoverers, *secretin*, possesses the specific property of stimulating the pancreatic cells to secrete: thus the production and translocation of secretin is a mechanism by which the outpouring of one of the most important of the digestive juices is co-ordinated with the entry of food into the portion of the gut into which it is discharged. To substances of such a kind Bayliss and Starling applied the term *hormone*. Schafer has also used the word *autacoid* for specific physiologically active, *i.e.*, drug-like substances which can be extracted from different organs of the body; as there are several autacoids whose role in the intact animal has not as yet been ascertained, the distinction is a valuable one.

Properties of Autacoids.—Of the specific physiologically active constituents of extracts in the ductless glands, adrenaline claims prior attention, since it was isolated in chemically pure form as early as 1902. Adrenaline is the active constituent of the chromaphil tissues of vertebrates; it also appears to be present in certain invertebrates, such as the mollusc *Purpura* and in the nerve ganglia of leeches. It is the only autacoid known with certainty to be present in the body of animals outside the vertebrate series. Injection into the circulation in all land vertebrates produces a marked rise of blood pressure due to arterial constriction. In the pupillary muscles it produces dilation. It produces contraction of the melanophores or black pigment cells in the skin of reptiles, amphibia and fishes. It causes stoppage of movement and loss of tone in intestinal muscle, generally inhibition of the bladder, acceleration of the heart in land vertebrates, and either inhibition or excitation of uterus muscle in mammals, depending on the species. The intestinal response is especially diagnostic and sensitive, being obtainable in dilutions from 1:20,000,000 to 1:800,000,000. In general there is a noteworthy parallelism between the effect of adrenaline and of sympathetic stimulation on the same structure; drugs which block the sympathetic impulse at the nerve-muscle junction antagonize the action of adrenaline. The pharmacological properties of the extracts of the pituitary body of vertebrates are manifold. The three most specific are: (a) Pressor activity, *i.e.*, prolonged rise of blood pressure followed by tolerance to successive injections in the mammal, as described by Oliver and Schafer; (b) Oxytocic activity, *i.e.*, powerful constrictor activity on the mammalian uterus discovered by Dale; (c) Pigmentary effector activity, *i.e.*, power to evoke expansion of amphibian melanophores studied by Hogben and Winton. The first of these is common to the pituitaries of all land vertebrates and bony fishes; the last two to extracts of the posterior lobe of all vertebrates. The activity of other organ extracts may be deferred to a consideration of the role of chemical co-ordination (*vide infra*).

Chemical Constitution of Autacoids.—Adrenaline was isolated in pure form independently by Takamine and Aldrich in 1902. It has since been synthesized, and an iodine compound first isolated in pure form by Kendall (1917) and later by Harrington (1927). Highly concentrated extracts of the pituitary (posterior lobe) have been prepared by Dudley and by Abel and his colleagues. The latter has obtained a preparation which constricts the mammalian uterus in a dilution of 1:1,250,000,000. Like insulin, the active constituents of the islets of Langerhans, and like secretin they are crystalloidal substances destroyed by trypsin; they are, therefore, possibly polypeptides.

Methods of Investigation.—Suggestive indications that an organ is one of internal secretion, in the sense defined above, is provided by a study of the biological action of these drug-like substances or autacoids extracted from certain tissues. Characteristic clinical or post operative consequences of disease, atrophy and removal also suggest lines of investigation. But either of these alone is inadequate as a criterion of endocrine activity. Fresh extracts of the pituitary gland of vertebrates have the property of raising the blood pressure. This is an important fact in pharmacology, since extracts of the pituitary have been used to ameliorate the condition of surgical shock, and the existence of this property of pituitary extracts naturally prompts investigation into the possible relation of the pituitary gland to the regulation of blood pressure in the mammal; but there is no justification for assuming without further evidence that such a relation exists. It is contrary to the principles of scientific method to assume that every chemical entity found in the body must necessarily be propitious to its efficient working. Again the fact that removal of the testis in the mammal prevents the assumption of the male secondary sexual characters does not of itself justify the common references in medical literature to an internal secretion of the testis. On this evidence alone, no economy of hypothesis is effected by assuming that the testis discharges specific exciting substances into the circulation in preference to the equally plausible alternative that it removes or neutralizes something.

The question of the regulation of active responses by chemical co-ordination is more accessible to experimental study. If it is known that an organ contains a substance which evokes a specific local reaction in some organ or response (muscle, gland, pigment cell, etc.) its endocrine function is sufficiently established by applying one of two methods. In some cases it is possible to show that reactions which follow administration of the organ extract are associated in the intact animal with the appearance of some substance in the blood, having similar chemical and biological properties to the active constituent of the extract. This line was pursued with the study of the adrenals, and it was formerly thought that the dilation of the pupil, quickening of the pulse, etc., characteristic of fright in the mammal, were not wholly of nervous origin but in part reinforced by liberation of adrenaline into the circulation. This view has been quoted widely and accepted by many psychologists. It appears, however, from later more quantitative observations of Stewart and his colleagues that the evidence of previous investigators was founded on inadequate technique. Stewart's work shows that small quantities of adrenaline do make their way into the circulation more or less continuously. Whether such small quantities are really significant to the efficient neuromuscular activity of the animal, and whether special conditions exist in which a large outpouring of adrenaline into the blood stream occurs is still uncertain. The method which has been applied in the study of adrenaline secretion is essentially similar to that which has been adopted in the study of pancreatic regulation by secretin formation, as mentioned above. An alternative method of investigation consists in compensating for the effects of removal of a supposedly endocrine organ by introducing its extract into the circulation. In the case of amphibia (frogs and salamanders), the black pigment cells responsible for the colour responses can be induced to expand after the injection of exceedingly minute traces of extract of the pituitary gland. Removal of the gland (posterior lobe) on the other hand results in a state of permanent pallor due to complete contraction of the pigment cells. Here the immediate agency involved in co-ordinating the synchronous response of the pigmentary effector organs of the skin with the external conditions that evoke colour response is evidently the secretion of the pituitary gland. In frogs removal of the gland results in the dilatation of the minute vessels (*capillaries*) of the skin, and Krogh has shown that perfusion of these vessels with a fluid containing a trace of pituitary extract results in their constriction. It is possible that the rise of blood pressure following injection in the mammal arises from the same reaction, and Krogh has obtained some evidence that pituitary secretion

regulates capillary tone in mammals as well as amphibia.

With regard to the part played by internal secretions in relation to chemical equilibrium and development, the attempt to harmonize the effects of removal of organs and of injecting their autacoids into the circulation has yielded the only significant data. First and foremost comes the thyroid. In man, under-development of the gland is associated with the infantile condition known as cretinism, and in later life with the disease known as myxoedema. Both of these are characterized among other things with a lower respiratory activity of the tissues, which is remedied with the clinical manifestations by injection of thyroxine. In frogs and salamanders the *larval* or tadpole stage can be induced to develop into the adult with amazing precocity by thyroid feeding or injection, and the total elimination of iodine from the water or removal of the thyroid gland prevent the larval form from assuming the adult condition, so that it remains permanently in the aquatic form. A few larval forms in nature such as the axolotl larva of the Mexican salamander become sexually mature and never ordinarily assume the adult form if kept in aquaria. The axolotl will develop into a land salamander within ten days of thyroid feeding. Removal of the anterior lobe of the pituitary gland in frog tadpoles has also been shown by P. E. Smith and Bennet Allen to prevent metamorphosis. In this case the thyroid remains underdeveloped. Thyroid feeding causes the tadpoles to mature, as does also injection of pituitary anterior lobe extracts, which induce the thyroid to attain its normal development. Thus pituitary secretion stimulates the development of the thyroid just as thyroid secretion promotes the assumption of the adult characters, and this interrelationship makes it easier to form a picture of the way in which the orderly chronological sequence in which new systems of organs make their appearance in the course of development is brought about. In man, disorders of the anterior lobe are associated with clinical abnormalities of development (acromegaly, etc.), which at present remain obscure. In regard to sexual development the main positive results have arisen in connection with ovarian extracts prepared first by Allen and his associates. Removal of the ovaries brings about cessation of the oestrous phenomena. Injection of ovarian extracts evokes oestrous activity, and Parkes has shown that menstruation in the human subject can be induced in this way. A great deal of interest has recently centred round the internal secretion of the pancreas. It has long been known that removal of the pancreas results in diabetes. In 1922 Banting and Best showed that the fatal results of removal of the pancreas can be prevented by specially prepared extracts of the gland, the active constituent of which has the power of lowering the sugar content of blood and urine. Collip has recently claimed that the lowered calcium content of the blood associated with clinical disorders of the parathyroid glands, or operative removal of the same, can be compensated by the injection of an extract of the gland.

Practical Results.—The successful use of thyroid extracts for myxoedema and cretinism, the application of pituitary extracts to promote contraction of the womb in obstetrical practice, and to raise blood pressure in cases of surgical shock, the use of adrenaline in superficial haemorrhage, and finally the importance of insulin in relation to diabetes represent genuine positive achievements of no mean value in modern scientific medicine. The manufacture of glandular preparations, however, has been abused for commercial purposes, and a great deal of what is called glandular therapy or organotherapy is based on no proper information. So-called polyglandular preparations are sold by a number of firms, and are extensively employed by medical men who have insufficient information at their disposal to sift the wheat from the chaff. Side by side with these abuses, descriptions of clinical manifestations, uncontrolled by critical experiment, has led to a large amount of speculation about the role of the ductless glands in determining differences of temperament. Much of this is passing into psychological and sociological works. It cannot be too strongly emphasized that, while such speculation may serve a useful purpose by stimulating further enquiry, it is for the most part entirely premature and often without any valid justification.

See L. T. Hogben, *The Comparative Physiology of Internal Secretion* (1927); E. Schafer, *The Endocrine Organs* (1924–26); S. Vincent, *Internal Secretion and the Ductless Glands* (1924). (L. T. H.)

ENDOEUS, an early sculptor, who worked at Athens in the middle of the 6th century B.C. We are told that he made an image of Athena dedicated by Callias, the contemporary of Pisistratus, at Athens about 564 B.C. An inscription bearing his name has been found at Athens, written in Ionian dialect. The tradition which made him a pupil of Daedalus is apparently misleading, since Daedalus had no connection with Ionic art.

ENDOGAMY. The law of endogamy prohibits the marriage of an individual outside his or her social group. It concerns itself with marriage only, not with extra-marital relations. The most famous example is among the Hindus who do not permit men and women of different castes to marry. (*See* CASTE.) Among primitive peoples it is rare, though in many parts of Africa the smiths do seem to form an endogamous occupational unit and the Santals of India punish breaches of the law. Where society is an hierarchy the disapproval of marriages between individuals of different classes may assume the form of a definite regulation, and this is true also of the feeling against a woman marrying outside her own tribe or local group, but such unions can generally be condoned, and diplomatic marriages between different tribes do take place.

Exogamy and endogamy are by no means mutually exclusive. In any community there may be one type of social group, *e.g.*, the clan, which is exogamous, and another type, *e.g.*, the occupational class, which is endogamous. This condition is actually found in India where the endogamous castes are composed of exogamous clans. Thus, exogamy and endogamy are often found together, supplementing one another. (*See* EXOGAMY.)

ENDOR, an ancient town of Palestine, situated in the territory of Issachar, and a place from which the Manassites could not expel the Canaanites (Josh. xvii. 11). It was the scene of the rout of Jabin and Sisera (Ps. lxxxiii. 9), but is chiefly memorable as the abode of the sorceress whom Saul consulted on the eve of the battle of Gilboa (I Sam. xxviii.). In the fourth century A.D. it is described as a large village four Roman miles south of Tabor. There is a village 'Endur (not 'Endur) in the locality indicated on the slope of Jebel Dhāhi, with burial caves, grain pits and rock-cut cisterns to attest to its ancient importance. From a cave a spring flows which waters the village gardens. (E. Ro.)

FIG. 1.—ENDOTHELIAL COVERING OF THE PERITONEAL MEMBRANE

ENDOTHELIUM. Lining the blood-vessels, the lymphatics and lymph spaces, and the pleural, pericardial, and peritoneal cavities are found flattened cells (endothelial cells) joined at their edges to form an extremely thin membrane.

An endothelial cell is very flattened and possesses a protoplasm with faint granules and an oval or round nucleus (figs. 1 and 2). The cells are irregularly polyhedral and united at the edges by cement substance which, though scanty, stains with silver nitrate when the appearance reproduced in the figure is seen. By being thus united together the cells form a continuous layer. In serous cavities this layer is pierced by small openings (stomata), which bring the cavity into communication with lymph spaces or vessels lying beneath the membrane. The stomata are surrounded by a special layer of cubical and granular cells.

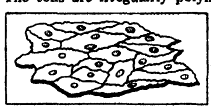

FIG. 2.—ENDOTHELIAL CELLS FROM INTERIOR OF AN ARTERY, STAINED BY NITRATE OF SILVER

By means of endothelial membranes the surfaces of the parts covered by them are rendered very smooth. Thus the abdominal organs can glide easily over one another within the peritoneal cavity; the blood or lymph experiences the least amount of fric-

tion, and friction is reduced to a minimum between a tendon and its sheath or in the joint cavities. The cells forming these membranes also possess further physiological properties. Thus it is most probable that they play an active part in the blood capillaries in transmitting substances from the blood into the tissue spaces, or conversely in preventing the passage of materials from blood to tissue space or from tissue space to blood. Hence the fluid of the blood and that of the tissue space need not be of the same chemical composition. Endothelial cells also may be phagocytic (*see* PHAGOCYTOSIS).

ENDOWMENT INSURANCE: *see* LIFE INSURANCE.

ENDYMION, in Greek mythology, son of Aëthlius and king of Elis. He was loved by Selene, goddess of the moon, by whom he had 50 daughters. Otherwise, he was a beautiful youth, a shepherd or hunter whom Selene visited every night while he lay asleep in a cave on Mount Latmus in Caria (Pausanias v., 1, 3; Ovid, *Ars am.* iii. 83). Zeus offered him anything he might desire, and he chose an everlasting sleep, in which he might remain youthful for ever (Apollodorus i. 56). According to others, Endymion's eternal sleep was a punishment inflicted by Zeus upon him because he ventured to fall in love with Hera (Schol. Theocritus iii. 49). The usual form of the legend, however, represents Endymion as having been put to sleep by Selene herself in order that she might enjoy his society undisturbed (Cicero, *Tusc. disp.* i. 92).

ENERGETICS may be defined as the science of energy. In systems whose state is changing so slowly that the reactions arising from changing motions can be neglected, whether these systems are in a stationary condition or in a state of steady motion, the energy depends upon the configuration alone, and its mathematical expression can be determined from measurement of the work required for a sufficient number of single transformations. Once it is found, all statical relations of the system are implicitly determined along with it, and results of all other transformations can be predicted. The general development of such relations are conveniently classed as a separate branch of physics under the name *Energetics* first proposed by J. M. Rankine. (*See* THERMODYNAMICS.)

ENERGICI or ENERGUMENS (Gr. "possessed by a spirit"), the name given in the early Church to those suffering from different forms of insanity, who were popularly supposed to be under the control of some indwelling spirit other than their own. Among primitive races everywhere disease is explained in this way, and its removal supposed to be effected by priestly prayers and incantations. They were sometimes called χειμαζόμενοι, as being "tossed by the waves" of uncontrollable impulse. Persons afflicted thus were forbidden to enter the church, but were daily fed and prayed for over by the exorcists, and, in case of recovery, after a fast of from 20 to 40 days, were admitted to the Eucharist, and their names and cures entered in the church records.

A note on the New Testament use of the word ἐνεργεῖν and its cognates will be found in J. A. Robinson's edition of *The Epistle to the Ephesians*, pp. 241–247; an excursus on "The Conflict with Demons" in A. Harnack, *The Expansion of Christianity*, i. 152–180. *Cf.* EXORCISM.

ENERGISM, a term introduced by F. Paulsen (*Introduction to Philosophy*, 1898) to express his conception of the moral ideal as consisting not in a condition of mere state of feeling (like happiness) but in a life devoted to a certain kind of activity or work. The term energism is also used sometimes to designate the ontological view which identifies ultimate reality, or the primal stuff or substance, with some kind of energy.

ENERGY, in physical science, a term which may be defined as accumulated mechanical work, which, however, may be only partially available for use (from the Gr. ἐνέργεια: ἐν, in ἔργον, work). A bent spring possesses energy, for it is capable of doing work in returning to its natural form; a charge of gunpowder possesses energy, for it is capable of doing work in exploding; a Leyden jar charged with electricity possesses energy, for it is capable of doing work in being discharged; a magnet is capable of attracting certain bodies (*e.g.*, iron) and doing work during their approach. The motions of bodies, or of the ultimate parts of bodies, also involve energy, for stopping them would be a source of work.

Measurement.—All kinds of energy are ultimately measured in terms of work. If we raise 1 lb. of matter through a foot we do a certain amount of work against the earth's attraction; if we raise 2 lb. through the same height we do twice this amount of work, and so on. Also, the work done in raising 1 lb. through 2 ft. will be double of that done in raising it 1 ft. Thus we recognize that the work done varies conjointly as the resistance overcome and the distance through which it is overcome.

Now, we may select any definite quantity of work we please as our unit, as, for example, the work done in lifting a pound a foot high from the sea-level in the latitude of London, which is the unit of work generally adopted by British engineers, and is called the "foot-pound." The most appropriate unit for scientific purposes is one which depends only on the fundamental units of length, mass and time, and is hence called an absolute unit. Such a unit is independent of gravity or of any other quantity which varies with the locality. Taking the centimetre, gramme and second as our fundamental units, the most convenient unit of force is that which, acting on a gramme for a second, produces in it a velocity of a centimetre per second; this is called a Dyne. The unit of work is that which is required to overcome a resistance of a dyne over a centimetre, and is called an Erg. In the latitude of Paris the dyne is equal to the weight of about $\frac{1}{981}$ of a gramme, and the erg is the amount of work required to raise $\frac{1}{981}$ of a gramme vertically through one centimetre.

Energy is commonly defined as the capacity for doing work. Since, however, we cannot always bring about the change the term capacity is somewhat misleading; it is better to define energy as that which diminishes when work is done by an amount equal to the work so done. The unit of energy should therefore be the same as that of work, and the centimetre-gramme-second (C.G.S.) unit of energy is the erg.

It will be seen from that which has been stated that energy may become manifest in many ways; or, in other words there are many forms of energy.

Forms.—The forms of energy which are most readily recognized are of course those in which the energy can be most directly employed in doing mechanical work; and it is manifest that masses of matter which are large enough to be seen and handled are more readily dealt with mechanically than are smaller masses. Hence when useful work can be obtained from a system by simply connecting visible portions of it by a train of mechanism, such energy is more readily recognized than is that which would compel us to control the behaviour of molecules before we could transform it into useful work. This leads up to the fundamental distinction, introduced by Lord Kelvin, between "available energy," which we can turn to mechanical effect, and "diffuse energy," which is useless for that purpose.

Potential Energy.—If a pound weight be suspended by a string passing over a pulley, in descending through 10 ft. it is capable of raising nearly a pound weight attached to the other end of the string, through the same height, and thus can do nearly 10 foot-pounds of work. The smoother we make the pulley the more nearly does the amount of useful work which the weight is capable of doing approach 10 foot-pounds, and if we take into account the work done against the friction of the pulley, we may say that the work done by the descending weight is 10 foot-pounds, and hence when the weight is in its elevated position we have at disposal 10 foot-pounds more energy than when it is in the lower position. It should be noticed, however, that this energy is possessed by the system consisting of the earth and pound together, in virtue of their separation, and that neither could do work without the other to attract it. The system consisting of the earth and the pound therefore possesses an amount of energy which depends on the relative positions of its two parts, on account of the latent physical connection existing between them. In most mechanical systems the working stresses acting between the parts can be determined when the relative positions of all the parts are known; and the energy which a system possesses in virtue of the relative positions of its parts, or its *configuration*, is classified as "potential energy," to distinguish it from energy of motion which

we shall presently consider. The word potential does not imply that this energy is not real; it exists in potentiality only in the sense that it is stored away in some latent manner; but it can be drawn upon without limit for mechanical work.

Kinetic Energy.—It is a fundamental result in dynamics that, if a body be projected vertically upwards *in vacuo*, with a velocity of v centimetres per second, it will rise to a height of $v^2/2g$ centimetres, where g represents the numerical value of the acceleration produced by gravity in centimetre-second units. Now, if m represent the mass of the body in grammes its weight will be mg dynes, for it will require a force of mg dynes to produce in it the acceleration denoted by g. Hence the work done in raising the mass will be represented by $mg{\cdot}v^2/2g$, that is, $\frac{1}{2}mv^2$ *ergs*. Now, whatever be the direction in which a body is moving, a frictionless constraint, like a string attached to the body, can cause its velocity to be changed into the vertical direction without any change taking place in the magnitude of the velocity. Thus it is merely in virtue of the velocity that the mass is capable of rising against the resistance of gravity, and hence we recognize that on account of its motion the body possessed $\frac{1}{2}mv^2$ units of energy. Energy of motion is usually called "kinetic energy."

A simple example of the transformation of kinetic energy into potential energy, and vice versa, is afforded by the pendulum. When at the limits of its swing, the pendulum is for an instant at rest, and all the energy of the oscillation is static or potential. When passing through its position of equilibrium, since gravity can do no more work upon it without changing its fixed point of support, all the energy of oscillation is kinetic. At intermediate positions the energy is partly kinetic and partly potential.

Available kinetic energy is possessed by a system of two or more bodies in virtue of the relative motion of its parts. Since our conception of velocity is essentially relative, it is plain that any property possessed by a body in virtue of its motion can be effectively possessed by it only in relation to those bodies with respect to which it is moving. If a body whose mass is m grammes be moving with a velocity of v centimetres per second relative to the earth, the available kinetic energy possessed by the system is $\frac{1}{2}mv^2$ ergs if m be small relative to the earth. But if we consider two bodies each of mass m and one of them moving with velocity v relative to the other, only $\frac{1}{4}mv^2$ units of work is available from this system alone. Thus the estimation of kinetic energy is intimately affected by the choice of our base of measurement.

Conservation of Energy.—When the stresses acting between the parts of a system depend *only* on the relative positions of those parts, the sum of the kinetic energy and potential energy of the system is always the same, provided the system be not acted upon by anything outside it. Such a system is called "conservative," and is well illustrated by the swinging pendulum above referred to. But there are stresses which depend on the relative *motion* of the visible bodies between which they appear to act. When work is done against these forces no full equivalent of potential energy may be produced; this applies especially to frictional forces, for if the motion of the system be reversed the forces will be also reversed and will still oppose the motion. It was long believed that work done against such forces was lost, and it was not till the 19th century that the energy thus transformed was traced; the conservation of energy has become the master-key to unlock the connections in inanimate nature.

The conception of work and of energy was originally derived from observation of purely mechanical phenomena, that is to say, phenomena in which the relative positions and motions of visible portions of matter were all that were taken into consideration. Hence it is not surprising that, in those more subtle forms in which energy cannot be readily or completely converted into work, the universality of the principle of energy, its conservation, as regards amount, should for a long while have escaped recognition after it had become familiar in pure dynamics.

It was pointed out by Thomson (Lord Kelvin) and P. G. Tait that Newton had divined the principle of the conservation of energy, so far as it belongs purely to mechanics. But what became of the work done against friction and such non-conservative forces remained obscure, while the chemical doctrine that heat was an indestructible substance afterwards led to the idea that it was lost. There was, however, even before Newton's time, more than a suspicion that heat was due to the motions of the ultimate parts of which bodies are built up. Francis Bacon expressed his conviction that heat consists of a kind of motion or "brisk agitation" of the particles of matter. In the *Novum Organum*, after giving a long list of the sources of heat, he says: "From these examples, taken collectively as well as singly, the nature whose limit is heat appears to be motion. . . . It must not be thought that heat generates motion or motion heat (though in some respects this is true), but the very essence of heat, or the substantial self of heat, is motion, and nothing else." It must not be forgotten, however, that early writers make no distinction between heat and temperature. No definiteness therefore can be attributed to such anticipations as this. It was only when Joseph Black showed that heat was something (distinct from temperature) which could be measured that the ground was cleared for bringing it into the mechanical scheme.

Rumford's Investigations.—The first vigorous effort to restore the universality of the doctrine of energy was made by Benjamin Thompson, Count Rumford, and was published in the *Phil. Trans.* for 1798. Rumford was engaged in superintending the boring of cannon in the military arsenal at Munich, and was struck by the amount of heat produced by the action of the boring bar upon the brass castings. In order to see whether the heat came out of the chips he compared the capacity for heat of the chips abraded by the boring bar with that of an equal quantity of the metal cut from the block by a fine saw, and obtained the same result in the two cases, from which he concluded that "the heat produced could not possibly have been furnished at the expense of the latent heat of the metallic chips."

Rumford then turned up a hollow cylinder which was cast in one piece with a brass six-pounder, and having reduced the connection between the cylinder and cannon to a narrow neck of metal, he caused a blunt borer to press against the hollow of the cylinder with a force equal to the weight of about 10,000 lb., while the casting was made to rotate in a lathe. By this means the mean temperature of the brass was raised through about 70° Fahr., while the amount of metal abraded was only 837 grains.

In order to be sure that the heat was not due to the action of the air upon the newly exposed metallic surface, the cylinder and the end of the boring bar were immersed in 18·77 lb. of water contained in an oak box. The temperature of the water at the commencement of the experiment was 60° F and after two horses had turned the lathe for 2½ hours the water boiled. Taking into account the heat absorbed by the box and the metal, Rumford calculated that the heat developed was sufficient to raise 26·58 lb. of water from the freezing to the boiling point, and in this calculation the heat lost by radiation and conduction was neglected. Since one horse was capable of doing the work required, Rumford remarked that one horse can generate heat as rapidly as nine wax candles burning in the ordinary manner.

Finally, Rumford reviewed all the sources from which the heat might have been supposed to be derived, and concluded that it was simply produced by the friction, and that the supply was inexhaustible. "It is hardly necessary to add," he remarks, "that anything which any insulated body or system of bodies can continue to furnish *without limitation* cannot possibly be *a material substance;* and it appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner that heat was excited and communicated in these experiments, except it be *motion*."

Transformation of Energy.—About the same time Davy showed that two pieces of ice could be melted by rubbing them together in a vacuum, although everything surrounding them was at a temperature below the freezing point. He did not, however, infer that since the heat could not have been supplied by the ice, for ice absorbs heat in melting, this experiment afforded conclusive proof against the substantial nature of heat.

Though we may allow that the results obtained by Rumford and Davy demonstrate satisfactorily that heat is in some way due to

motion, yet they do not tell us to what particular dynamical quantity heat corresponds. For example, does the heat generated by friction vary as the friction and the time during which it acts, or is it proportional to the friction and the distance through which the rubbing bodies are displaced—that is, to the work done against friction—or does it involve any other conditions? If it can be shown that, however the duration and all other conditions of the experiment may be varied, the same amount of heat can in the end be always produced when the same amount of *energy* is expended, then, and only then, can we infer that heat is a form of energy, and that the energy consumed has been really transformed into heat. This was left for J. P. Joule to achieve; his experiments conclusively prove that heat and energy are of the same nature, and that all other forms of energy can be transformed into an equivalent amount of heat.

Mechanical Equivalent of Heat.—The quantity of energy which, if entirely converted into heat, is capable of raising the temperature of the unit mass of water from 0° C to 1° C is called the mechanical equivalent of heat.

In 1842 R. Mayer, a physician at Heilbronn, published an attempt to determine the mechanical equivalent of heat from the heat produced when air is compressed. Mayer made an assumption that the whole of the work done in compressing the air was converted into heat, and neglecting the possibility of heat being consumed in doing work within the air itself or being produced by the transformation of internal potential energy. Joule afterwards proved (*see* below) that Mayer's assumption was nearly in accordance with fact, so that his method was a sound one as far as experiment was concerned; and it was only on account of the values of the specific heats of air at constant pressure and at constant volume employed by him being very inexact that the value of the mechanical equivalent of heat obtained by Mayer was very far from the truth.

Joule's Researches.—Passing over L. A. Colding, who in 1843 presented to the Royal Society of Copenhagen a paper entitled *Theses concerning Force*, we come to Dr. James Prescott Joule of Manchester, to whom we are indebted more than to any other for the establishment of the principle of the conservation of energy on the broad basis on which it has since stood. The best-known of Joule's experiments was that in which a brass paddle consisting of eight arms rotated in a cylindrical vessel of water containing four fixed vanes, which allowed the passage of the arms of the paddle but prevented the water from rotating as a whole. The paddle was driven by weights, and the temperature of the water was observed by thermometers which could indicate $\frac{1}{200}$ of a degree Fahrenheit. Special experiments were made to determine the work done against resistances outside the vessel of water, which amounted to about ·006 of the whole, and corrections were made for the loss of heat by radiation, the buoyancy of the air affecting the descending weights, and the energy dissipated, *i.e.*, converted into heat, when the weights struck the floor with a finite velocity. From these experiments Joule obtained 72·692 foot-pounds in the latitude of Manchester as equivalent to the amount of heat required to raise 1 lb. of water through 1° Fahr., from the freezing point. Adopting the centigrade scale, this gives 1,390.846 foot-pounds.

With an apparatus similar to the above, but smaller, made of iron and filled with mercury, Joule obtained results varying from 772·814 foot-pounds when driving weights of about 58 lb. were employed to 775·352 foot-pounds when the driving weights were only about 19½ lb. By causing two conical surfaces of cast-iron immersed in mercury and contained in an iron vessel to rub against one another when pressed together by a lever, Joule obtained 776·045 foot-pounds for the mechanical equivalent of heat when the heavy weights were used, and 774·93 foot-pounds with the small driving weights. In this experiment a great noise was produced, corresponding to a loss of energy, and Joule endeavoured to determine the amount of energy necessary to produce an equal amount of sound from the string of a violoncello and to apply a corresponding correction.

The close agreement between the results at least indicated that "the amount of heat produced by friction is proportional to the work done and independent of the nature of the rubbing surfaces." Joule inferred from them that the mechanical equivalent of heat is probably about 772 foot-pounds, or, employing the centigrade scale, about 1,390 foot-pounds.

In 1840 he further showed that when an electric current was produced by means of a dynamo-magneto-electric machine the heat generated in the conductor, when no external work was done by the current, was the same as if the energy employed in producing the current had been converted into heat by friction, thus showing that electric currents conform to the principle of the conservation of energy, since energy can neither be created nor destroyed by them. He also determined a roughly approximate value for the mechanical equivalent of heat from the results of these experiments. He also extended his investigations to the currents produced by batteries.

In 1844 and 1845 Joule published a series of researches on the compression and expansion of air. A metal vessel was placed in a calorimeter and air forced into it, the amount of energy expended in compressing the air being measured. Assuming that the whole of the energy was converted into heat, when the air was subjected to a pressure of 21·5 atmospheres Joule obtained for the mechanical equivalent of heat about 824·8 foot-pounds, and when a pressure of only 10·5 atmospheres was employed the result was 796·9 foot-pounds.

In the next experiment the air was compressed as before, and then allowed to escape through a long lead tube immersed in the water of a calorimeter, and finally collected in a bell jar. The amount of heat absorbed by the air could thus be measured, while the work done by it in expanding could be readily calculated. In allowing the air to expand from a pressure of 21 atmospheres to that of 1 atmosphere the value of the mechanical equivalent of heat obtained was 821·89 foot-pounds. Between 10 atmospheres and 1 it was 815·875 foot-pounds, and between 23 and 14 atmospheres 761·74 foot-pounds.

But, unlike Mayer, Joule was not content with assuming that when air is compressed or allowed to expand the heat generated or absorbed is the equivalent of the work done and of that only, no change being made in the internal energy of the air itself when the temperature is kept constant. To test this two vessels similar to that used in the last experiment were placed in the same calorimeter and connected by a tube with a stop-cock. One contained air at a pressure of 22 atmospheres, while the other was exhausted. On opening the stop-cock no work was done by the expanding air against external forces, since it expanded into a vacuum, and it was found that no heat was generated or absorbed. This showed that Mayer's assumption was practically true. The subsequent researches of Dr. Joule and Lord Kelvin (*Phil. Trans.*, 1853, p. 357, 1854, p. 321, and 1862, p. 579) showed that the statement that no *internal work* is done when a gas expands or contracts is not quite true, but the amount is very small in the cases of those gases which, like oxygen, hydrogen and nitrogen, can only be liquefied by intense cold and pressure. (*See* LIQUEFACTION OF GASES.)

Subsequent Determinations.—For a long time the final result deduced by Joule by these varied and careful investigations was accepted as the standard value of the mechanical equivalent of heat. Recent determinations by H. A. Rowland and others, necessitated by modern requirements, have shown that it is in error, but by less than 1%. The writings of Joule, which thus occupy the place of honour in the practical establishment of the conservation of energy, have been collected into two volumes published by the Physical Society of London. On the theoretical side the greatest stimulus came from the publication in 1847, without knowledge of Mayer or Joule, of Helmholtz's great memoir, *Über die Erhaltung der Kraft*, followed immediately (1848–1852) by the establishment of the science of thermodynamics (*q.v.*), mainly by R. Clausius and Lord Kelvin on the basis of "Carnot's principle" (1824), modified in expression so as to be consistent with the conservation of energy.

The general equation of thermodynamics consistent with the above investigations may be written: Heat entering a system = Increase of energy of the system plus the external work done by

the system during the entry. It is clear from this that it is erroneous to speak of the heat *in* a body. Heat can pass inwards or outwards but the amount so passing is not a measure of the change of energy of the body for some of it passes out simultaneously as external work. The language in common use is an inheritance from the old caloric theory according to which heat was regarded as a substance. When heat passes into a solid or liquid very little external work is done and the usual nomenclature is fairly satisfactory. But it is essential to an understanding of thermodynamics to realize that it is not satisfactory in general. This subject is further considered in THERMODYNAMICS (*q.v.*).

Tendency of Transformations.—It may, however, be added here that in all cases there is a general tendency for other forms of energy to be transformed into heat on account of the friction of rough surfaces, the resistance of conductors, or similar causes, and thus to lose availability. In some cases, as when heat is converted into the kinetic energy of moving machinery or the potential energy of raised weights, there is an ascent of energy from the less available form of heat to the more available form of mechanical energy, but in all cases this is accompanied by the transfer of other heat from a body at a high temperature to one at a lower temperature, thus losing availability to an extent that more than compensates for the rise.

Recent theoretical developments in physics have given rise to the presumption that the law of conservation of energy as usually understood is valid only for small motions such as are met with in engineering problems. For the modifications necessary to obtain a general theory applicable to all cases reference must be made to the article on RELATIVITY (*q.v.*). (W. GAR.; J. LA.)

ENFANTIN, BARTHÉLEMY PROSPER (1796–1864), French social reformer, one of the founders of the Saint-Simonian School, was born at Paris on Feb. 8, 1796. He was the son of a banker of Dauphiny, and after receiving his early education at a lyceum, was sent in 1813 to the École Polytechnique. In 1821 he entered a banking-house newly established at St. Petersburg, but returned two years later to Paris, where he was appointed cashier to the Caisse Hypothécaire. At the same time he became a member of the secret society of the Carbonari. In 1825 a new turn was given to his thoughts and his life by the friendship which he formed with Olinde Rodriguez, who introduced him to Saint-Simon. He embraced the new doctrines with ardour, and by 1829 had become one of the acknowledged heads of the sect (*see* SAINT-SIMON).

After the revolution of 1830 Enfantin devoted himself wholly to his cause. Besides contributing to the *Globe* newspaper, he made appeals to the people by systematic preaching, and organized centres of action in some of the principal cities of France. The headquarters in Paris were removed from the modest rooms in the rue Taranne, and established in large halls near the boulevard Italien. Enfantin and Bazard (*q.v.*) were proclaimed "Pères Suprêmes." A hopeless antagonism arose between them, which was widened by Enfantin's announcement of his theory of the relation of man and woman, which would substitute for the "tyranny of marriage" a system of "free love." Bazard now separated from his colleague, and in his withdrawal was followed by all those whose chief aim was philosophical and political. Enfantin thus became sole "father," and the few who were chiefly attracted by his religious pretensions and aims still adhered to him. New converts joined them, and Enfantin declared that his followers in France numbered 40,000. In May 1832 the halls of the new sect were closed by the government, and the "father," with some of his followers, appeared before the tribunals. He now retired to his estate at Menilmontant, near Paris, where with 40 disciples, all of them men, he continued to carry out his socialistic views. In August of the same year he was again arrested, and sentenced to a year's imprisonment with a small fine.

Enfantin was released in a few months, and then, accompanied by some of his followers, he went to Egypt where he spent two years. On his return to France he became first a postmaster near Lyons, and in 1841 was appointed member of a scientific commission on Algeria. In 1845 he was appointed a director of the Paris and Lyons railway. Three years later he established, in conjunction with Duveyrier, a daily journal, entitled *Le Crédit*, which was discontinued in 1850. He died suddenly at Paris on Sept. 1, 1864.

Amongst his works are: *Doctrine de Saint-Simon* (written in conjunction with several of his followers), published in 1830, and several times republished; *Économie politique et politique Saint-Simonienne* (1831); *Correspondance politique* (1835–1840); *Corresp. philos. et religieuse* (1843–1845); *Colonisation de l'Algérie* (1843), a learned and original work; and *La Vie éternelle passée, présente, future* (1861). *See* G. Weill, *L'École Saint-Simonienne, son histoire, son influence, jusqu' à nos jours* (Paris, 1896).

ENFIDAVILLE [*Dar-el-Bey*], a town of Tunisia, on the railway between Tunis and Susa, 30 m. N.E. of the last-named place and 5 m. inland from the Gulf of Hammamet. Enfidaville is the chief settlement on the Enfida estate, a property of over 300,000 acres in the Sahel district of Tunisia, forming a rectangle between the towns of Hammamet, Susa, Kairawan and Zaghwan. On this estate, devoted to the cultivation of cereals, olives, vines and to pasturage, are colonies of Europeans and natives.

The Enfida estate was granted by the bey Mohammed-es-Sadok to his chief minister Khaireddin Pasha (*q.v.*) in return for the confirmation by the sultan of Turkey in 1871, through the instrumentality of the pasha, of the right of succession to the beylik of members of Es-Sadok's family. When, some years later, Khaireddin left Tunisia he sold the estate to a Marseilles company, which resold it to the Société Franco-africaine.

ENFIELD, a market town and urban district in the Enfield parliamentary division of Middlesex, England, 11 m. N. of London Bridge, with stations on the Great Northern and Great Eastern sections of the L.N.E. railway. Pop. of urban district (1921) 60,738. Enfield lies at the northern extremity of the county, extending westward from the Lea and Stort Navigation, and comprises the four local divisions known as the Town, in the centre, with the Chase on the west, and Green Street and Bull's Cross (with Ponders End, Enfield Highway and Enfield Lock) along the Old North Road on the east. It has grown rapidly as a residential and industrial area; many of the inhabitants are employed in the Royal Small Arms factory at Enfield Lock. The church of St. Andrew, mainly Perpendicular, with Early English portions, contains several ancient monuments and brasses. Enfield Palace, fronting the High Street, retains portions of the building of Edward VI. The grammar school for boys, founded in 1557, is now enlarged and modernized, with the county school for girls, under the joint control of the county and district councils. The New River flows through the parish, and Sir Hugh Myddleton, its projector, was for some time resident here. Enfield Chase, once a royal preserve, was disafforested in 1777, and largely enclosed thereafter. Several fine mansions in splendidly timbered parks remain, as Trent Park, Forty Hall and White Webbs. Forty Hall is from the designs of Inigo Jones; White Webbs was suspected as the scene of the hatching of the Gunpowder Plot. The urban council has control of over 200 ac. of parks and open spaces, including Hilly-fields (65 ac.), Bush Hill (27 ac.) and Enfield Town (23 ac.) parks.

An Anglo-Saxon derivation, signifying "forest clearing," is indicated for the name. The principal manor of Enfield, which was held by Asgar, Edward the Confessor's master of horse, was in the hands of Geoffrey de Mandeville at the time of Domesday, and belonged to the Bohun family in the 12th and 13th centuries. It came, by succession and marriage, into the possession of the crown under Henry IV., and was included in the duchy of Lancaster. Of the other manors, Worcesters came to the crown in the time of Henry VIII., whose children resided at the manor-house, Elsynge Hall. Edward VI., settling both manors upon the princess Elizabeth, rebuilt Enfield Palace for her. She was a frequent resident here before and after her accession to the throne. About 1664 the palace was occupied as a school by Robert Uvedale (1642–1722), who was also an eminent horticulturist. The town received grants of markets from Edward I. and James I.

ENFIELD, a town of Hartford county, Connecticut, U.S.A., on the east bank of the Connecticut river, 20m. N. of Hartford; served by the New York, New Haven and Hartford railroad. The population in 1920 was 11,719. The town has an area of

35 sq.m. and embraces several villages, of which Thompsonville is the largest and most important. Tobacco is grown, and there are various manufactures, notably carpets (the largest plants in the country) and casket hardware. Enfield was settled in 1679, and was included in the town of Springfield until 1683. In 1749 it became part of Connecticut. At a town meeting on July 11, 1774, a resolution was adopted in favour of breaking off "all commercial intercourse with Great Britain and the West Indies until these oppressive acts for raising a revenue in America are repealed." A Shaker community was established in 1781 at what is now Shaker Station.

ENFILADE, a military term used to express the direction of fire along an enemy's line from its flank. (A French word, from *enfiler*, to thread, and so to pass through from end to end.) This species of fire is most demoralizing and destructive as it rakes the greatest length of a position or body of troops, while only a fraction of the latter can reply to it. If any considerable body of men changes front, it immediately lays itself open to enfilade from the enemy whom it originally faced. Against entrenchments, or the parapets of fortifications, enfilade is still more effective, as the enemy is deprived of the protection given by his works and is no better covered than if he were in the open. Banks of earth (called *traverses*), built at right angles to the line of defence, are usually employed to protect parapets or trenches against enfilade.

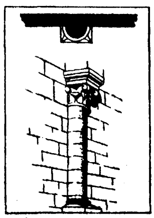
ENGADINE (Ger. *Engadin;* Ital. *Engadina;* Latin, *Engiadina*), the name of the upper or Swiss portion of the valley of the Inn, which forms part of the Swiss canton of the Grisons. Its length from the Maloja plateau (5,935 ft.) at its south-western end to Martinsbruck (3,406 ft.) at its north-eastern extremity is about 60 m. Up to and including St. Moritz (6,037 ft., the highest) all the villages (save Sils-Baseglia) at its south-western end are higher than the Maloja plateau itself. The uppermost portion of the valley contains several lakes, such as those of Sils, Silvaplana and St. Moritz. But both the Maloja plateau and the south-western half of the lake of Sils belong to the commune of Stampa in the Val Bregaglia, and are included in the Bregaglia administrative district, so that Sils is the first village included in the Engadine. The rest of the Engadine forms the districts of the Upper Engadine with 11 communes, and of the Inn (*i.e.*, the Lower Engadine), subdivided into the Ob Tasna, Remüs, and Unter Tasna circles, and containing 12 communes. The population (1920) was about 12,000, most of whom are Protestants. The capital of the Upper Engadine is Samaden, and that of the Lower Engadine, Schuls. The valley is reached by many passes. The Maloja (5,935 ft.) is the route from Chiavenna and the Lake of Como to the Upper Engadine, which is also reached from Coire by the Julier (7,504 ft.) and the Albula passes (7,595 ft.) as well as from Tirano in the Valtellina by the Bernina pass (7,645 ft.). On the other hand, the Lower Engadine is accessible from Davos over the Flüela pass (7,838 ft.) and from Mals at the head of the Adige valley (or the Vintschgau) by the Ofen pass (7,071 ft.), while from Martinsbruck, the last Swiss village, a road leads up to Nauders (5 m.), whence it is 27 m. by road down the Inn valley to Landeck, or 17½ m. over the Reschen Scheideck pass (4,902 ft.) to Mals in the Vintschgau.

The Upper Engadine, is not mentioned until 1139, when the bishop of Coire was the great lord, with the Planta family at Zuz as his bailiffs. The valley obtained its freedom from both in 1486 (Planta) and in 1526, when the temporal powers of the bishop were abolished. In 1367 it joined the newly founded League of God's House or *Gotteshausbund* (*see* GRISONS), one of the three Raetian Leagues, which lasted till 1799–1801, when the whole Engadine became part of Canton Raetia of the Helvetic Republic, which, in 1803, altered its name to that of Grisons or Graubünden, and then first entered the Swiss Confederation. In the Upper Engadine the "Referendum" existed as between the different villages composing a bailiwick (*Hochgericht*). The Lower Engadine formed from the 9th century onwards (with the Vintschgau) a separate county, which was gradually absorbed in that which became the county of Tirol. The limit between the Upper Engadine and the Tirolese Lower Engadine was definitively fixed in 1282 at the Punt' Ota just above Brail. In 1363 Tirol came into the possession of the Habsburgers, whose power was stemmed in 1499 at the battle of the Calven gorge (above Mals), though it was only in 1652 that the Lower Engadine bought up the remaining rights of the Habsburgers. But the castle of Tarasp (acquired by them in 1464) was excepted: the lordship was given by them in 1687 to the Dietrichstein family, who held it till 1801, when Austria ceded it to France, which, in 1803, handed it over to the Swiss Confederation; it was incorporated in 1809 with the Canton of the Grisons. This long connection with Tirol accounts for the fact that Tarasp is still mainly Roman Catholic, while the lonely Swiss valley of Samnaun (above Martinsbruck) has given up its Protestantism and its Ladin speech owing to communications with Tirol being easier than with Switzerland. The upper Spöl valley (Livigno) is Italian (*see* VALTELLINA).

The Upper Engadine consists of a long, straight, nearly level trough of 26 m., varying from a mile to half a mile in breadth, through which flows the Inn. On the south-east this trough is limited by the glacier-clad Bernina group (culminating in the Piz Bernina, 13,304 ft.) and the range rising between the Inn valley and that of Livigno to the south-east, while on the north-west the boundary is the extensive Albula group (culminating in Piz Kesch, 11,228 ft.). On its north-west rises the last bit of the Albula group (culminating in Piz Vadret, 10,584 ft.); and on the north the Silvretta group (culminating in Piz Linard, 11,201 ft.), while to the east and south are the ranges on either side of the Ofen pass (culminating in Piz Sesvenna, 10,568 ft.). In the Upper Engadine the villages are on the floor of the valley, but in the Lower Engadine many are perched high above the bed of the river on terraces, and are cut off from each other by deep valleys.

The mineral waters of St. Moritz (*q.v.*) were known in the 16th century, and long formed the great attraction of the region. In the 19th century the Upper Engadine came into fashion as a great "air-cure," and now Maloja, Sils, Silvaplana, Campfer and St. Moritz are all well known. Owing to its great elevation, the scenery of the Upper Engadine has a bleak, northern aspect. Pines and larches alone flourish, garden vegetables are grown only in sunny spots, and there is no tillage. The Alpine flora is very rich and varied. But snow falls even in August. The villages are built entirely of stone (as also in the Lower Engadine), chiefly to guard against destructive fires that were formerly frequent in this narrow, wind-swept valley. The wealth of the inhabitants consists in their hay meadows and pastures. The lower pastures support large herds of cows, while the higher are let out (in both parts of the valley) to Bergamasque shepherds, who come thither every summer with their flocks. In the Lower Engadine the chief attraction is formed by the mineral springs at Schuls below Tarasp, which are much frequented during the summer. The wild gorge of Finstermünz separates the last Swiss village, Martinsbruck, from the first Tirolese village, Pfunds, the gorge being passable only on foot.

The Swiss National park, an area of 54 sq.m., is in the Lower Engadine.



ENGAGED COLUMN

ENGAGED COLUMN, in architecture, a structure taking the form of a column partly embedded in a pier or wall, a half or three-quarter column attached to a pier or wall face. Engaged columns are usually built integrally with the wall of the building of which they form a part, but occasionally, due to the use of the lathe, they are made of separate stones, and in woodwork are almost always separate pieces glued or nailed in place. Engaged columns occur rarely in Greek work, as in the temple of Zeus at Agrigentum (*c.* 500 B.C.); they are, however, common in Roman buildings. As a wall decoration they are occasionally used in temple walls where colonnades are only at the front, as in the temple of Fortuna Virilis, in Rome (*c.* 150 B.C.), and the Maison Carré at Nimes (time of Tiberius). Their most common use is to decorate the piers of arcades, as in the Colosseum at Rome (A.D. 80), and this combination of arch and engaged column is

sometimes termed the Roman order. In mediaeval architecture, engaged columns frequently form the component parts of clustered piers. They are common in all Renaissance styles.

ENGEL, ERNST (1821–1896), German economist and statistician, was born in Dresden on March 16, 1821. After the revolution of 1848 he was attached to the royal commission in Saxony appointed to determine the relations between trade and labour. He was one of the organizers (1850) of the German Industrial Exhibition of Leipzig (the first of its kind). From 1854 to 1858 he was head of the statistical department of Saxony, and from 1860 to 1882 of the Prussian statistical department in Berlin. He died at Radebeul near Dresden on Dec. 8, 1896. Engel's statistical papers are mostly published in the periodicals which he himself established, viz. *Preuss. Statistik* (in 1861); *Zeitschrift des Statistischen Bureaus*, and *Zeitschrift des Statistichen Bureaus des Königreichs Sachsen*. Among his separately published works are some important studies on wages and the cost of living.

ENGEL, JOHANN JAKOB (1741–1802), German author, was born at Parchim, Mecklenburg, on Sept. 11, 1741. He was tutor (1786–94) to the crown prince of Prussia, afterwards Frederick William III., and (1787–94) director of the royal theatre. He died on June 28, 1802.

Engel's most popular work was *Der Philosoph für die Welt* (1775), dialogues on men and morals, written from the utilitarian standpoint. His last work, a romance entitled *Herr Lorenz Stark* (1795), achieved a great success.

His collected works were published in 12 volumes (1801–06); a new edition appeared at Frankfort in 1851. *See* K. Schröder, *Johann Jakob Engel* (1897).

ENGELBERG, Alpine village and valley in central Switzerland, much frequented by visitors in summer and winter. It is 14 m. by electric railway from Stansstad, on the Lake of Lucerne. Pop. (1920) 2,310, practically all German-speaking and Romanists. The village (3,343 ft.) is shut in on all sides by lofty mountains (the highest is the Titlis, 10,627 ft. in the south-east), so that it is often hot in summer. It communicates by the Surenen pass (7,563 ft.) with Wassen, on the St. Gotthard railway, and by the Joch pass (7,267 ft.) past the favourite summer resort of the Engstlen Alp (6,034 ft.), with Meiringen in the Bernese Oberland. The village has clustered round the great Benedictine monastery which gives its name to the valley, from the legend that its site was fixed by angels ("Mons Angelorum"). The monastery, founded about 1120 still survives, though the buildings date only from the 18th century. Its library suffered much at the hands of the French in 1798. From 1462 onwards it was under the protectorate of Lucerne, Schwyz, Unterwalden and Uri. In 1798 the abbot lost his temporal powers, and his domains were annexed to the Obwalden division of Unterwalden, but in 1803 were transferred to the Nidwalden division. In 1816 the valley was again transferred to Obwalden, part of which it still forms. As the pastures forming the upper portion of the Engelberg valley have for ages belonged to Uri, the actual valley itself is politically isolated between Uri and Nidwalden.

ENGELBRECHTSDATTER, DORTHE (1634–1716), Norwegian hymn-writer, was born at Bergen on Jan. 16, 1634 and died on Feb. 19, 1716. The first of her volumes of sacred verse, *Sjaelens aandelige Sangoffer* (Copenhagen, 1678), was the best. Her collected works have passed through many editions.

ENGELHARDT, JOHANN GEORG VEIT (1791–1855), German theologian, was born at Neustadt-on-the-Aisch on Nov. 12, 1791, and was educated at Erlangen, where he afterwards taught in the gymnasium (1817), and became professor of theology in the university (1821). His great works were a *Handbuch der Kirchengeschichte*, 4 vols. (1833–34), and a *Dogmengeschichte* in 2 vols. (1839). He died at Erlangen on Sept. 13, 1855.

ENGELS, FRIEDRICH (1820–1895), German socialist, the friend and collaborator of Karl Marx, was the son of a wealthy cotton-spinner, and was born on Sept. 28, 1820, at Barmen. Although destined by his father for a commercial career, he attended a classical school, and during his apprenticeship and whilst undergoing in Berlin his one year's military service, he had given up part of his free hours to philosophical studies. In Berlin he had frequented the society of the "Freien," and had written letters to the *Rheinische Zeitung*. In 1842 he had gone to England, his father's firm having a factory near Manchester, and had entered into connection with the Owenite and Chartist movements, as well as with German communists. He contributed to Owen's *New Moral World* and to the Chartist *Northern Star*, gave up much of his abstract speculative reasoning for a more positivist conception of things, and took to economic studies. In September 1844, on a short stay in Paris, he visited Marx, and the two found that in regard to all theoretical points there was perfect agreement between them. From that visit dates the close friendship and uninterrupted collaboration and exchange of ideas which lasted during their lives, so that even some of Marx's subsequent works, which he published under his own name, are more or less also the work of Engels. He took part in the Baden revolutionary outbreak in 1848, and after its suppression fled to England. From 1850 to 1869 he worked in his father's business in Manchester, but in 1870 went to London to devote himself entirely to literary work. In 1864 he married Elizabeth Burns, an Irishwoman. He died in London on August 5, 1895. An account of his co-operation with Marx and an examination of his share in Marx's writings, with a list of his own works, is given *s.v.* Marx, Karl Heinrich, on account of the difficulty of dissociating their joint shares.

See D. Riazanor, *Marx and Engels* (London, 1927); Gustav Meyer, *Friedrich Engels*, vol. i. (1920).

ENGHIEN, LOUIS ANTOINE HENRI DE BOURBON CONDÉ, Duc d' (1772–1804), was the only son of Henri Louis Joseph, prince of Condé, and of Louise Marie Thérèse Mathilde, sister of the duke of Orleans (Philippe Égalité), and was born at Chantilly on Aug. 2, 1772. He was educated privately by the abbé Millot, and received a military training from the commodore de Virieux. In 1792, on the outbreak of war, he held a command in the force of *émigrés* (styled the "French royal army") which shared in the duke of Brunswick's unsuccessful invasion of France. On the dissolution of that force after the peace of Lunéville (Feb. 1801) he married privately the princess Charlotte, niece of Cardinal de Rohan, and took up his residence at Ettenheim in Baden, near the Rhine. Early in the year 1804 Napoleon, then first consul of France, heard news which seemed to connect the young duke with the Cadoudal-Pichegru conspiracy then being tracked by the French police. The news ran that the duke was in company with Dumouriez and made secret journeys into France. This was false; the acquaintance was Thuméry, a harmless old man, and the duke had no dealings with Cadoudal or Pichegru. Napoleon gave orders for the seizure of the duke. French mounted gendarmes crossed the Rhine secretly, surrounded his house and brought him to Strasbourg (March 15, 1804), and thence to the castle of Vincennes, near Paris. There a commission of French colonels was hastily gathered to try him. The duke was now charged chiefly with bearing arms against France in the late war, and with intending to take part in the new coalition then proposed against France. The colonels hastily and most informally drew up the act of condemnation, being incited thereto by orders from Savary (*q.v.*), who had come charged with instructions. The duke was shot in the moat of the castle, near a grave which had already been prepared. With him ended the house of Condé. In 1816 the bones were exhumed and placed in the chapel of the castle. It is now known that Josephine and Mme. de Rémusat had begged Napoleon for mercy towards the duke; but nothing would bend his will. The blame which the apologists of the emperor have thrown on Talleyrand and Savary is undeserved.

See H. Welschinger, *Le Duc d'Enghien 1772–1804* (Paris, 1888) and *L'enlèvement d'Ettenheim et l'exécution de Vincennes* (1913); A. Nougaret de Fayet, *Recherches historiques sur le procès et la condemnation du duc d'Enghien*, 2 vols. (Paris, 1844); Comte A. Boulay de la Meurthe, *Les Dernières Années du duc d'Enghien 1801–1804* (Paris, 1886). For documents see *La Catastrophe du duc d'Enghien* in the edition of *Mémoires* edited by M. F. Barrière, also the edition of the duke's letters, etc., by Count Boulay de la Meurthe (tome i., Paris, 1904; tome ii., 1908).

ENGHIEN, a town in the province of Hainaut, Belgium, lying south of Grammont. Pop. estimated 5,000. It is the centre

of considerable lace, linen and cotton industries. The great Condé was given, for a victory gained near this place, the right to use the style of Enghien among his subsidiary titles.

ENGINE, a mechanical tool or contrivance. In the 19th century the term came to have, when employed alone, a specific reference to the steam engine, but it is also used of other prime movers such as the internal combustion engine. For accounts of the various types of engines *see:* STEAM ENGINE; INTERNAL COMBUSTION ENGINE; DIESEL ENGINE; TURBINE, STEAM; TURBINE, WATER; MARINE ENGINEERING; LOCOMOTIVE; REFRIGERATION; AIR ENGINE; FIRE ENGINE.

ENGINEER, PROFESSIONAL. So diversified are the services required of professional engineers throughout the wide range of industries, public utilities and governmental work, and in the discovery, development and conservation of resources, that men of extremely various personality and physique may achieve success. Qualifications include intellectual and moral honesty, courage, independence of thought, fairness, good sense, sound judgment, perseverance, resourcefulness, ingenuity, orderliness, application, accuracy and endurance. An engineer should have ability to observe, deduce, apply, to correlate cause and effect, to co-operate, to organize, to analyze situations and conditions, to state problems, to direct the efforts of others. He should know how to inform, convince and win confidence by skillful and right use of facts. He should be alert, ready to learn, open-minded, but not credulous. He must be able to assemble facts, to investigate thoroughly, to discriminate clearly between assumption and proven knowledge. He should be a man of faith, one who perceives both difficulties and ways to surmount them. He should not only know mathematics and mechanics, but should be trained to methods of thought based on these fundamental branches of learning. Organized habits of memory and large capacity for information are necessary. He should have extensive knowledge of the sciences and other branches of learning and know intensively those things which concern his specialties. He must be a student throughout his career and keep abreast of human progress.

Having been endowed more or less completely with qualifications and capacities requisite for a professional engineer and having developed them with the aid of educational and other institutions and contacts provided by civilized communities, the engineer is under obligation to consider the sociological, economic and spiritual effects of engineering operations and to aid his fellowmen to adjust wisely their modes of living, their industrial, commercial and governmental procedures, and their educational processes so as to enjoy the greatest possible benefit from the progress achieved through our accumulating knowledge of the universe and ourselves as applied by engineering. The engineer's principal work is to discover and conserve natural resources of materials and forces, including the human, and to create means for utilizing these resources with minimal cost and waste and with maximal useful results. (*See* CIVIL, ELECTRICAL, MECHANICAL, MINING and ENGINEER, and CHEMICAL ENGINEERING.)

(A. D. F.)

ENGINEERING in its early uses referred specially to the operations of those who constructed engines of war and executed works intended to serve military purposes. Such military engineers were long the only ones to whom the title was applied. But about the middle of the 18th century there began to arise a new class of engineers who concerned themselves with works which, though they might be in some cases, as in the making of roads, of the same character as those undertaken by military engineers, were neither exclusively military in purpose nor executed by soldiers, and those men by way of distinction came to be known as civil engineers. No better definition of their aims and functions can be given than that which is contained in the charter (dated 1828) of the Institution of Civil Engineers (London), where civil engineering is described as the "art of directing the great sources of power in nature for the use and convenience of man, as the means of production and of traffic in states, both for external and internal trade, as applied in the construction of roads, bridges, aqueducts, canals, river navigation and docks for internal intercourse and exchange, and in the construction of ports, harbours, moles, breakwaters and lighthouses, and in the art of navigation by artificial power for the purposes of commerce, and in the construction and adaptation of machinery, and in the drainage of cities and towns." Wide as is this enumeration, the practice of a civil engineer in the earlier part of the 19th century might cover many or even most of the subjects it contains. But gradually specialization set in. Perhaps the first branch to be recognized as separate was *mechanical* engineering, which is concerned with steam-engines, machine tools, mill-work and moving machinery in general, and it was soon followed by *mining* engineering, which deals with the location and working of coal, ore and other minerals. Subsequently numerous other more or less strictly defined groups and subdivisions came into existence, such as marine, sanitary, chemical and electrical engineering.

ENGINEERING AND ARCHITECTURAL SOCIETIES. The principal English society dealing with mechanical science is the *Institution of Civil Engineers* (established in 1818, incorporated in 1828), which publishes *Transactions* (4to, 1836–1842) and *Minutes of Proceedings* (8vo, 1837, etc.). George Stephenson was the first president of the *Institution of Mechanical Engineers,* which was founded at Birmingham in 1847, removed to London in 1877, and registered under the Companies Act in 1878. It holds migratory meetings and publishes *Proceedings.* The *Society of Engineers* (1854), with *Transactions* (1861, etc.); The *Civil and Mechanical Engineers' Society* (1859); the *Iron and Steel Institute* (1869, incorp. 1899), with *Journal* and *Mem.;* the *Surveyors' Institution* (1868, incorporated in 1881), which publishes *Transactions* and holds professional examinations; the *Aeronautical Society of Great Britain* (1866), the *Institution of Electrical Engineers* (1871, incorp. 1883), *Journal;* the *Institution of Mining Engineers* has associated with it many branch institutions in the provinces, *Journal;* the *Institute of Gas Engineers* (1863); the *Illuminating Engineers' Soc.* (1909); the *Institute of Metals;* and the *Instn. of Mining and Metallurgy,* meet in London. There are institutions in the provinces at Bradford, Bristol, Cardiff (1857, incorp. in 1881), Chesterfield (1871), Dublin (1835, incorp. in 1857), Glasgow (1857, with *Transactions*), *Liverpool* (1875), Middlesbrough (1864), Newcastle-upon-Tyne (1852, incorp. in 1876, with *Transactions*), Nottingham (1871), Dudley (1866), and Belfast (1892).

The leading architectural society is the *Royal Institute of British Architects,* founded in 1834, incorporated in 1837, and granted new charters in 1887 and 1908. It appoints examining professional boards and publishes *Transactions* (1836; 1879, etc.) and *Proceedings* (1879, etc.). There are also the associations of Birmingham (1873), Edinburgh (1850), Exeter (1843), Glasgow (1868), Leeds (1876), Leicestershire (1855), Liverpool (1848), Manchester (1875), Newcastle-upon-Tyne, and the societies of Manchester (1865) and Oxford (1837). The *Architectural Association* of London publishes a *Sketch Book* (1870, etc.). The *Architectural Publishing Society* (1848) has published *Essays* (1848–1852), and since 1852 has been bringing out a *Dictionary of Architecture.* There is also a *Society of Architects* (1884, incorp. 1893). The *Roy. Inst. of Architects of Ireland* meets in Dublin and publishes a *Journal.*

ENGINEERING ARTICLES. For articles on prime movers *see* ENGINE, which gives reference to the various orders of engines. For articles on the different forms in which engineering is concerned with the application of power to traffic on land and sea and in the air, a key will be found under the heading TRANSPORT. The application of power to industry leads to a specialization of engineering in respect of each separate industry, and for an account of this the reader should turn to the articles on various industries; *e.g.*, BRIDGES, BOILER, AERONAUTICS, RAILWAYS, PRINTING, WEAVING, GAS MANUFACTURE and PAPER MANUFACTURE.

Electrical engineering is the subject of a special group of articles, amongst which may be named ELECTRICAL POWER GENERATION, ELECTRICAL POWER TRANSMISSION, ELECTRICITY SUPPLY, ELECTRIFICATION OF INDUSTRY and ELECTRIC FURNACE. For the articles on power transmission, by various means, reference should be made to the key given under that heading. The important subject of mining engineering will be found under the headings MINING, METALLIFEROUS; COAL AND COAL MINING; BORING; BLASTING, etc.; and under various subject headings such as COPPER, LEAD, GOLD, SILVER, etc. For hydraulic engineering, reference should be made to the articles HYDRAULICS; HYDRAULIC MACHINERY; HYDRO-ELECTRIC GENERATION; and TURBINE, WATER. In its application to shipping, the articles MARINE ENGINEERING and SHIPBUILDING should be consulted.

The application of engineering to the chemical trades will be found treated under the wide series of articles dealing with chemical products, including DYES; ALKALI MANUFACTURE; ARTIFICIAL SILK; NITROGEN, FIXATION OF. The engineering connected with natural and artificial waterways, seaports, etc., is of great importance and is treated in a group of articles which cover, *inter alia*, RIVER ENGINEERING, CANALS, DOCKS, DAMS, HARBOURS, BREAKWATER, JETTY and PIER. There are also special articles on LOCK, DOCKS, FLOATING, LIGHTHOUSE and LIGHTSHIP.

ENGINEERING EDUCATION. Engineering education to-day embraces instruction and training not only in the older divisions of civil, mechanical, mining and electrical engineering, and their subdivisions—highway engineering, harbour engineering, automobile engineering, machine tool engineering, structural engineering, illuminating engineering, etc., but also in such allied branches as chemical engineering and metallurgical engineering. In spite however of modern specialisation a sound knowledge of the principles and methods of general science is becoming ever more necessary as engineering becomes more scientific. The general history of the growth of engineering education is to be found in the articles on Technical Education and Polytechnics (*q.v.*), but special reference may be made to George Birkbeck (1776–1841), who founded, in 1823, the "Mechanics Institute" afterwards known as Birkbeck college (University of London), and to the later action of the great Companies of the City of London in founding the City and Guilds of London Institute. The Central Technical college, South Kensington, now part of the Imperial College of Science and Technology, proved a most important foundation, while grants of money to provincial centres and the establishment of "City of Guilds" examinations and certificates in technology paved the way for national schemes. In 1880 Mr. Quintin Hogg founded the Regent Street Polytechnic (London), the success encouraging the opening of numerous provincial "industrial institutes." In university engineering education the way was led by Cambridge, but engineering degrees are now granted by London, Manchester, Sheffield, Birmingham, Newcastle and other universities.

Aims and Standards of Engineering Education.—The principal aims of engineering education should be: (1) To train those who will later be "Captains of Industry" (2) To train the rank and file of the industrial army by enabling them to perform their allotted tasks with greater proficiency and interest, while avoiding the perils of "blind alley" employment.

The introduction of automatic and semi-automatic machinery has made it difficult to acquire craftsmanship in many branches of industry. Fortunately, the peril has been realized. Trade schools for practical instruction are available in most districts, and no young workman should rest content till he has mastered a trade. Even if forced to undertake routine work, he will be all the better for being a skilled craftsman, and his proficiency will stand him in good stead in emergencies.

Preliminary General Education.—For those who will form the great mass of the industrial army of workers, a good primary education is sufficient preliminary preparation, but it should embrace elementary science and such broad subjects as nature study in order that the men and women concerned may have a greater interest in their work and its results, as well as "outside" interests. Those who have a prospect of entering the higher ranks of engineering should seek a good general education on the Modern side, in French, German and science, while a few will benefit by carrying this education a stage higher into the university sphere.

Special Diplomas in Engineering Education.—For those unable to take the university course, certain special diplomas have been created. Thus, in Great Britain, the Sheffield university recognizes as Associates in Metallurgy those who attain a high standard in metallurgical work, with only a preliminary examination in English and chemistry. This diploma is highly valued.

Assistance by Employers.—Much can be done by individual employers to encourage the spread of education among their younger people. Thus Hadfields Limited (Sheffield) has for many years had a scheme based upon refunding the entrance fees of those, under 21 years of age, who secure 75% attendance marks in certain recognized courses, technical and commercial, at the secondary schools or university evening classes. A bonus of 1s. per week is also paid throughout the following year for each subject (up to three in number) in which 75% attendance has been registered and a first-class certificate obtained. During the session 1927–28, about 70% of the students had their fees refunded, and nearly 40% earned an average bonus of £3. 13s. 4d.

Educational Influence of Engineering Institutions.—The great engineering institutions—such as those of civil, of mechanical, and of electrical engineers—have also done much to raise the standard of engineering education. The qualifications demanded for associate membership cover a high degree of proficiency in engineering theory, and a considerable term of practical employment in a responsible position. Membership of such institutions may be considered as equivalent to a university degree.

Suggestions to Students.—(i.) Full attention should be paid by the student to health, physical exercise and social intercourse. Good health and good citizenship are invaluable. (ii.) In every grade of education, most importance should be attached to the underlying principles. Knowledge only becomes valuable when *applied*. Learn, therefore, how to use works of reference, papers before engineering societies, and other stores of accumulated facts; and acquire the habit of applying principles rather than formulae. (iii.) Those who seek the highest positions should have a broad and sound general education. They must be prepared to continue their studies and investigations, even if unaided, during the whole of their active career. (iv.) For the rest a good secondary or primary education according to their intended employment is necessary. Their chances of rising to supervisory grades will increase according to their assiduity in acquiring an intelligent grasp of the reasons underlying their work. (v.) Between the ages of 16 to 21 years, those who hope to qualify as at (iii.) above should, if possible, take advantage of university

courses with a view to a degree or an equivalent diploma. This, again, must be supplemented by practical experience and ability. Mention should also be made here of "sandwich" schemes where the student spends alternate periods of work at some higher institution during his years of apprenticeship, an idea, first started in Sunderland, which certainly gives excellent results. (vi.) Those unable to take the higher courses in education should attend the continuation evening classes available in almost every district.

The Future.—On the whole, the provisions for engineering education in England may be described as excellent and, indeed, second to none. Nevertheless the following improvements seem feasible.

(a) *Monotony of Routine Work.*—A large proportion of those in industrial employment are obviously obliged to remain at the bench, machine or forge throughout their working life. Such need a further education to widen their interests in life. Unfortunately the curricula of many evening classes have not always been suitable. This however is likely to be largely remedied by the Committee on Technical Education for the Engineering Industry recently appointed by Lord Eustace Percy (Great Britain).

(b) *"Blind Alley" Employment.*—Further education including technical education is still more necessary for those who take on those "blind alley" occupations which are an inseparable part of mass production to-day.

(c) *"Individuality" in Research.*—The professional staffs of universities and colleges may usefully engage in research work in pure science, in their spare time; but it is rarely possible for any educational institution to do much in the way of industrial research. The experience and equipment which can be brought to bear on its research problems by any properly organized industrial establishment are naturally greater.

(d) *Science at the Helm.*—Science and engineering are so closely associated with every phase of modern life that a reasonable proportion of the members of central and local authorities responsible for educational policy should themselves have been trained in science and engineering. The policy of the British Board of Education to-day is to delegate increasing responsibility to local authorities in the adaptation of instruction to local requirements, thus averting the consequences which might result from the predominance of classically trained persons in Government Departments.

Conclusion.—The arrangements for engineering education in Great Britain, as already stated, are second to none. Every prospective entrant to the industry should ascertain what provisions for scientific and technical training are made in his district. But he should also remember that the facilities alone can accomplish nothing. The tools of education are ready to hand but those who would use them must work long and hard. (R. Ha.)

THE UNITED STATES

In the American Colonies all industries except agriculture and the production of raw materials were repressed by the British parliament. After the Revolutionary War, a struggle for industrial independence ensued. Societies for the promotion of the useful arts were formed, premiums were offered for useful improvements and trained artisans from abroad were sought. The feeling that the sciences through a new type of education should aid the industries seems to have found first expression in a truly technical school in 1822 under Benjamin Hale at Bowdoin college in Maine. Though it lived but a decade, its purpose, scope and plans have found fruit in the modern engineering school.

In 1824, Stephen Van Rensselaer established at Troy, N.Y., the Rensselaer Polytechnic institute, the oldest of present engineering schools. Initially it was a school for teaching "the sons and daughters of farmers and mechanics" the application of science "to agriculture, domestic economy, the arts and manufactures." Depletion of the soil led to early emphasis on agricultural problems. General engineering soon appeared, and in 1829 civil engineering, the degree being first conferred in 1835. The plan of studies was remodelled in 1849 on the technical lines of the École Centrale of Paris and covered three years. The Rensselaer Polytechnic institute and the U.S. Military academy at West Point were for many years the only schools affording scientific training. Their graduates were a potent factor in making the highways, bridges, canals and railroads essential to the development of the country. Rensselaer graduates have been leaders in scientific and engineering activities and in engineering education.

In 1847 the Lawrence Scientific school at Harvard and the Sheffield Scientific school at Yale were established and in 1853 the University of Michigan offered a course in civil engineering. In 1862, Congress passed the Morrill Act granting land to the States for colleges of agriculture and mechanic arts. The four engineering schools of 1860 increased to 17 by 1870 and to 85 in 1880, about half being land grant colleges (*q.v.*) The others were formed as parts of existing universities, or were independent. This rapid increase was responsive to the industrial trend; in the 50 years prior to 1870 the proportion of the country's working population engaged in manufacture, trade, transportation and professional service increased about threefold.

In its beginning, engineering instruction was included in the term civil engineering. Courses in mining and mechanical engineering formally appeared in the '60s. Civil, mining and mechanical engineering were based on the experience of many generations. In the '80s came electrical and a decade later chemical engineering based upon new sciences. To the technical graduate is largely due the outstanding progress in these fields. Accumulating scientific and technical knowledge has lead to differentiation and subdivision, until there are two score and more engineering courses, offshoots of the initial civil engineering. The usual engineering curriculum, following the four year secondary school course, contains three groups of subjects, scientific (mathematics, physics, chemistry), technical (relating to a specific field of engineering and its allied fields), and non-technical (English, history, social science). The scientific and non-technical subjects are usually substantially similar in the several engineering curricula, differentiation occurring in the technical content of the later years. The degree of bachelor of science, with or without specification of a particular branch, is commonly conferred at the end of four years, while the professional degree, such as civil engineering, is generally reserved for graduate work.

The enrolment in 148 engineering schools in the United States on Nov. 1, 1927, is reported by the U.S. Bureau of Education as 63,023 regular undergraduates (of which 10,073 were seniors) and 1,669 post-graduates. The number of seniors and post- graduates in the larger groups were: electrical, 3,051 and 468; civil, 2,323 and 266; mechanical, 1,855 and 240. Engineering education in America had its beginning under the auspices of educational scientists and professional educators rather than professional engineers or Government bureaux as in Europe. Conventional methods proved inadequate and the engineering colleges in many localities and under many leaders and with changing industrial conditions have been notable organizers in developing a new type of education. They have combined scientific, technological and humanistic subjects in a unified balanced curriculum, introduced the individual method of laboratory instruction and incorporated shop work in the college programme. Shop work has had different aims and has taken different forms: construction shops, as developed at Sibley college and Cornell university; manufacturing shops, with remuneration to students; shop laboratories for teaching principles of industrial production. In lieu of shops the laboratory is supplemented by systematic inspection of industries or by the co-operative plan inaugurated at the University of Cincinnati in which students alternate between school activities and industrial employment. Engineering schools have promoted research, they have organized engineering experiment stations and they have co-operated with industry in various ways.

Fifty years development of engineering education has witnessed a rising status of the engineer. In place of a single feeble national engineering society, there are now several, large and vigorous, with a total enrolment (1928) of some 60,000. But engineering is not as restricted and definite as law or medicine. The engineer sometimes renders service which is technical and specific, but often it involves also contracts and business relations, construction and

management. Much engineering is done by groups rather than by individuals; modern industry employs engineers for co-ordinated work on a large scale; scientific training and technical experience qualify young engineers for dealing with managerial, commercial and financial, as well as purely technical, problems. There is a progressive trend of engineering graduates toward managerial duties. Years ago the demand upon the schools was for trained experts; now it is for men of broad outlook, well grounded in fundamentals, trained in methods of scientific analysis and intellectually capable of progressing through continued studies and a novitiate of practical experience to leadership in various fields, appropriate to their aptitudes and abilities. Prior to about 1900 electrical engineers, for example, were designing and perfecting their apparatus; recently there has come the application of electric service to a thousand uses in transportation and manufacture, in the mine, on the farm and in the home. The versatile and scientifically trained engineering graduate has been an active factor in increasing the use of electricity each decade and making the power industry one of the largest in the investment of new capital and in its economic and social importance.

The Society for the Promotion of Engineering Education was organized in 1893, as a pioneer movement by a professional group for the betterment of education by bringing engineering teachers into helpful contact. It inaugurated a movement by the engineering societies "to examine into all branches of engineering education" which resulted in a report by Dr. C. R. Mann, *A Study of Engineering Education* (1918), under the auspices of the Carnegie Foundation for the Advancement of Teaching. In 1923 the society undertook a new study under its board of investigation and co-ordination with financial support from the Carnegie Corporation, industries and individuals. The engineering schools cooperated actively in a fact-finding survey as to teachers, students, graduates, curricula, costs and the need for improvements. The results of the survey with accompanying comment have appeared in the *Journal of Engineering Education*, and separately issued reports which present the status and trend in engineering education to-day have been made available. (C. F. S.)

ENGINEERING INDEX, a non-commercial card index issued weekly to subscribers by the American Society of Mechanical Engineers. It contains the title and a short abstract of articles appearing in 1,700 technical publications, representing 37 countries. Every phase of engineering activity is covered under 13 main classifications and 118 sub-classifications. All articles that are listed have been read and reviewed by prominent engineering authorities. Any particular division or subdivision may be subscribed for.

ENGINEERING INSURANCE. The use of machinery involves manufacturers in certain special risks which are undertaken by engineering insurance companies. Unlike most other classes of insurance, which are designed to indemnify the insured after he has suffered loss, engineering insurance endeavours primarily to reduce the possibility of a loss occurring. To this end insured machinery is periodically inspected by skilled engineers to ascertain defects before they result in an explosion of, or breakdown in, the plant. A very large proportion of the premiums received is expended upon these services, which enable the insured to receive the advice of experts as to methods of obtaining the utmost economy and efficiency from the plant.

The Factory Acts stipulate that all boilers under pressure must be periodically examined by competent engineers, and in the event of explosion an enquiry will be instituted by the board of trade, or similar authority out of England, under the Boiler Explosions acts to ascertain its cause. The inspections thus rendered essential are undertaken by the insurers in the terms of the boiler policy, which also indemnifies the insured in respect of claims made against him by third parties in respect of personal injuries and covers damage to surrounding property caused by the explosion. Law costs incurred with the consent of the insurers in defending claims are also included.

Policies are not confined solely to boilers, whether under pressure or not, but are issued for all classes of plant working under pressure. Insurances are sought extensively for such items as superheaters, calorifiers, hot water and steam heating boilers with heating pipes and radiators and other vessels working under steam, liquid, air or gas pressure.

In connection with cast-iron sectional low pressure boilers, the risk of cracking of sections and of explosion and cracking pipes may be insured, whilst in approved cases water damage to surrounding property following leakage may be covered.

Breakdown risks of gas, oil and steam engines and power gas plants are commonly insured and subject to the exclusion of certain inexpensive parts, the breakage of any part of a machine proper whilst running, causing a sudden stoppage of the machine and necessitating repair before work can be resumed, is covered. No compensation is payable for loss of use under this type of policy. Whilst gas and oil engine policies include an indemnity in respect of damage due to flying fragments caused by the breakdown, such cover is not provided under the steam engine policy unless specifically insured. Periodical inspections of the plant are followed by the despatch of engineers' reports to the insured containing advice as to its use, although non-compliance with the suggestions made does not invalidate the contract.

Lift insurance covers the risk of liability to third parties for personal injuries due or alleged to be due to defects, or to negligence of attendants, in connection with the lift, its gates, hatchways or shaft. Whilst lift accidents are fortunately infrequent, they are usually attended by serious results followed by substantial claims upon the lift owners for damages. The ordinary lift policy does not include the risk of damage to property, although it may occasionally be covered by special arrangement with the insurers. The proposal form requires full details of the lift to be insured and the proposer is required to indicate the limits of indemnity required in respect of (a) any one person, (b) any one accident, and (c) any one year of insurance. The indemnity selected is generally inclusive of any law costs which may be payable to claimants, but law costs incurred in the defence of the insured are invariably paid by the insurers in addition. The policy stipulates for the quarterly inspection of the lift by skilled engineers and, whilst the insured may select the engineer, subject to the insurers' approval, engineering insurance companies are willing to undertake these services.

Policies similar in principle are issued in respect of hoists and cranes, although the premiums required are frequently greater, having regard to the increased possibility of goods falling upon third parties, particularly when such devices overhang public thoroughfares. Cranes of certain types are liable to collapse and also to toppling risks which may be specifically insured under a special form of policy.

Time loss policies guarantee the payment to the insured of a fixed sum per day to cover the loss of time consequent upon the breakdown of engines, explosion of boilers, or the collapse of flues. Normally the first 48 hours after each breakdown is excluded. Immediate notice must be given to the company of any breakdown, and, as these policies are only issued in conjunction with the appropriate damage or breakdown insurances, the insurers make arrangements for repairs.

Engineering insurance companies are also prepared to undertake inspections of plant for valuation and sale purposes and in many cases superintend the manufacturing processes. Chemical analysis of water for use in boilers in different districts and tests regarding water softeners are also undertaken.

(A. G. M. B.)

UNITED STATES

Fundamentally insurance means the acceptance of a risk of loss for a premium and the payment of that loss if it arises. In this sense there is no such thing as engineering insurance in the United States. Engineering insurance is furnished as a policy service, but not as an insurance or contract undertaking. This service is safety engineering and in its application to insured risks it is commonly called "inspection." In America risks are written which are made up of boilers and machinery, the machinery risks being limited largely to prime movers. This risk group has been sometimes improperly called "engineering in-

surance." A majority of underwriters appear to favour the term "power plant insurance." Insurance is by policy contract, and safety engineering is a voluntary service for the policy holder. Power-plant insurance includes: boiler insurance covering explosion of vessels and piping subject to internal pressure; engine insurance covering the breakdown of prime movers and some accessories; wheel insurance covering the breakdown of fly- or transmission-wheels or other rotating parts which may include shafting; electrical machinery insurance covering the breakdown of electrical transmitters and accessories.

Safety Engineering.—The obvious duties of safety engineers are to prevent losses, and that is true of all lines. Safety engineering (*see* INDUSTRIAL ACCIDENTS, PREVENTION OF) has practically become a profession in the United States and constant efforts are made to apply to safety problems all obtainable skill and knowledge. In the fields mentioned above the duties of the safety engineer are particularly exacting, because resulting losses are by no means limited to the thing particularly insured but involve remote and indirect losses of many kinds, such as damage to the property of others, injuries to persons, use and occupancy losses and spoiling of product because of enforced suspension. This suspension is not always due to machinery within the plant, but may be covered for failure of power furnished from the outside by public utilities and others. The safety engineer cannot hope to prevent remote losses except by preventing loss to the thing insured or against failure of outside power sources. In the early days the companies prepared plans and specifications for boilers and other pressure containers, but this has been largely superseded by the standardized plans of the American Society of Mechanical Engineers. The safety engineering force usually includes one or more chemists who test boiler water and suggest chemical treatment to avoid scale or possible rupture. The general practice is to provide in the policy contract for the *privilege* of inspection by the company's safety engineers.

The most extensive, and probably the most promising, field for safety engineering grows out of the relation between employers and employees. This is particularly true under the workman's compensation laws. There are workman's compensation laws with varying provisions in all States except five. This means that there are 43 different compensation laws to which effective safety engineering practice must be adapted. Practically all companies work upon the theory that an injury prevented is a benefaction, an injury compensated an apology. It would be impossible within reasonable limits to undertake a detailed explanation of this line of safety work. Policy holders are usually advised not only upon mechanical safety but also on sanitation, light, heat and ventilation. Insurance companies assist in the forming of safety organizations in industrial plants, and instruct the members of such organizations in safety principles.

A feature of this form of loss which is not generally recognized is of particular interest to the employer. The loss due to a personal injury is only a small part of the loss which the employer actually sustains. The indirect losses due to the excitement naturally caused by an accident, the general stoppage of work for a time by a considerable part of the force and the temporary loss of *moral* have been demonstrated as losses amounting to several times as much as the direct loss because of the accidental injury, and these collateral losses cannot be insured because of their nature. Insurance companies generally have no right to enforce their safety recommendations, and their only recourse is cancellation.

Extent of Practice.—This engineering practice is not limited to shops or other fixed work places, but extends to a very large number of fields. The construction operations of contractors, for instance, involve special safety engineering work, and this is also true of mining activities. Insurance companies assume no engineering control over construction, but merely keep the operation, as such, under constant observation to prevent accidents. The companies in the United States undertake many kinds of public liability insurance. These are frequently concurrent with workmen's compensation or employers' liability, yet very often they are written alone. General property damage (meaning liability for damage to the property of others) is written usually with as much freedom as the laws permit in connection with public liability lines. The service of the safety engineer is required principally where there are concurrent types of insurance policies, but may be required in any one of them. Elevator insurance requires special safety engineering work, usually applied at stated intervals during the term of the policy. This class of insurance may include personal injury, property damage and collision. In automobile insurance policies the services of the safety engineer are principally directed to fleets where five or more commercial automobiles are in the same ownership or operation. The companies form safety groups among the employees and instruct them on various occasions. Automobile insurance includes personal injury, property damage, collision, fire and theft.

Plate-glass insurance involves no collateral risk, the loss being limited to the particular glass insured. The U.S. companies generally use a surveyor rather than an engineer, although the surveyor has sufficient engineering training to report upon safety conditions. Many companies write policies where the obligation is direct to the policy holder without any question as to liability. In fire policies the companies consider safety engineering important. The obvious purpose is to prevent fires, and recommendations are not usually influenced by probable rate reduction. The safety engineer gives attention to sprinkler systems, location of supply tank, exposure of head to heat sources, defective flues, defective wiring, etc. Burglary insurance with its collateral types is written quite extensively by United States companies and here safety engineering finds an important field. In "mercantile open stock" insurance the safety engineer is called upon to study the best known methods of protection. Apartment house risks receive some attention by the safety engineer particularly as respects door and window locks and fire-escapes. Sprinkler leakage and also various kinds of water damage, including that caused by plumbing, provide a field for the safety engineer in various directions. (W. G. C.)

ENGINEERS, MILITARY. The earliest history of the military engineer is the history of primeval warfare, when every man was a fighter and every fighter to some extent an engineer. Primitive efforts were restricted to the provision of artificial protection for the person and machines for hurling destruction at the enemy. To these activities were added road and bridge building. With the invention of gunpowder came the era of great fortresses and the rise of the technical expert, to whom the great scientific discoveries of the 19th century brought ever-increasing responsibilities; so that, in modern armies, there is scarcely a problem of civil, mechanical or electrical engineering with which the military engineer may not be called upon to grapple. The cost of providing separately for each branch of engineering is prohibitive; and in European armies, with compulsory service and well-marked military frontiers, the tendency has been to confine the engineers to their traditional functions of fortification and siege-craft, depending on the civil departments for such technical services as might be required. To the voluntary service army of Great Britain, such a system is unsuitable, and the need for a corps of all-round engineers has been recognized. Men of all engineering trades are included in its ranks, while the officers after receiving a general scientific education, are liable to serve in any unit of the corps and, by means of periodical changes of employment, are ensured wide practical experience. As history always repeats itself, so the present mechanical era seems likely to reproduce a state in which every soldier will again be, in some wise and of necessity, an engineer.

FROM EARLIEST DATE TO THE WORLD WAR

Great Britain.—In earliest war annals it is difficult to distinguish the military from the civil engineer. Julius Caesar refers to his "praefectus fabrum," an official who controlled the labour gangs employed on road-making and also parties of artisans. The Domesday survey of A.D. 1086 includes one "Waldivus Ingeniator," who held nine manors direct from the Crown, and was probably William the Conqueror's chief engineer. Throughout the middle ages ecclesiastics were frequently employed as military

engineers; not only for purposes of planning and building, but also for fighting. The best known is Gundulph, bishop of Rochester, a famous engineer of his day, who built the White tower of the Tower of London (1078) and Rochester castle. For labour civil artificers were engaged, principally carpenters, wood-cutters and sappers (fossatores) for road-making. In A.D. 1300 the name *Attillator* was given to the official responsible for the maintenance of permanent works of defence, and for manipulating the engines of war. This title, at the time synonymous with "engineer," may perhaps be the origin of "artillery." Headquarters of engineers existed at the Tower of London before A.D. 1350, and a century later developed into the Office (later Board) of Ordnance, whose duty was to administer all matters concerned with fortification, artillery and ordnance stores. The first English record of the employment of engineers and artillery in a siege is in A.D. 1346, when Edward III. was before Calais; the wages roll numbered 31,294, of whom 314 were engineers, gunners and other artificers. Edward III. believed in using trained artificers and he collected experienced miners from the Forest of Dean, also smiths and others from the City of London. The records of later sieges show similarly that bodies of carpenters, miners, labourers and smiths were employed, *cf.* Harfleur A.D. 1415. During the 15th century there are few references to engineers. In A.D. 1513 Henry VIII. appointed a "Master Trenchermaster," who later became "Master of the Ordnance." He also separated combatant engineers from those who merely constructed works; the former were appointed for campaigns only and were entitled "Trenchmaster," or "Captain of the Pioneers"; they had no control over the artillery, which was under a master of the ordnance, also appointed for the campaign, and usually himself an engineer. Those entrusted with the construction of permanent works were called "Surveyors of the King's Works," or sometimes "Master Masons." During this reign "Pioneers" were for the first time organized in regular corps during active operations. Henry VIII. gave much work to his engineers, and the numbers being insufficient, many foreigners, especially Italians and Spaniards, were brought to England; his fear of invasion gave special impetus to work on coast defences. Henry's best known chief engineer was Sir Richard Lee. Elizabeth introduced the title "Lieutenant of the Ordnance," which was borne by Sir William Pelham, the most distinguished engineer of her reign. The title of surveyor fell into disuse about the middle of the 17th century, when that of engineer again became general for both combatant and non-combatant branches. A new division gradually appeared (the King's Engineers) permanently appointed and patented, who were charged with the design, construction and inspection of the fortifications of the country; and engineers appointed to the trains that were formed for war and included all branches of the ordnance; viz., engineers, artillery and store or munitions branch. The commander of the train was usually the chief engineer. The duties of the board of ordnance were first clearly defined by royal warrant in 1683, when the principal engineer was made responsible for the efficiency and attainments of the members of his branch. Previously each individual officer had corresponded direct with the board of ordnance, ministers or other authorities. At the end of the 17th century the train included guns, howitzers, grenades, pontoons, tents, entrenching and artificers' tools, scaling ladders and mining timber; the men were formed into a mortar detachment, gun detachment, company of bridgemen, artificers, store and transport attendants; the whole being commanded by the senior engineer.

The artillery and engineers were separated in 1716, when two companies of artillery and a corps of engineer officers were established, all under the board of ordnance. The system of appointment to the corps of engineers remained that of patronage. There was no academy, no examination, no competition. A code of instructions issued in 1740 shows that the engineers were still supposed to exercise a great measure of control over the artillery; the number of guns, their siting, mounting and protection, all lying within the province of the engineers. The Royal Military Academy, Woolwich, was founded by royal warrant in 1741, on the demand of the board of ordnance, in order "to instruct the raw and inexperienced people of this office in the several parts of Mathematicks necessary to qualify them for the service of the artillery and the business of engineers." The first record of engineers in India is in 1747, when a warrant was issued for a train to accompany the expedition under Admiral Boscawen; in 1773, by a warrant of the king, engineers serving in India ceased to be members of the corps.

The year 1747 saw the commencement of the military survey of Scotland, which was undertaken as a preliminary to the invasion of the Highlands. This was entrusted to the corps of engineers and became the precursor of the Ordnance Survey, which remains to this day under control of Royal Engineer officers. At that period engineer officers had no recognized military rank or status, unless, as occasionally happened, they were granted commissions in other regiments, or on the staff. This was naturally unsatisfactory and had long been a grievance. Direct appeal was at last made by the officers to H.R.H the duke of Cumberland, Captain-General of the Forces, at which the board of ordnance was highly incensed. In 1757, after nearly ten years of friction and argument, military rank was formally approved; no warrant can be traced, but every engineer officer received a signed commission from the king. Thirty years later the title of the corps was changed to its present one of "Royal Engineers," and it was authorized to take precedence with the artillery on the right of the line. No regular units or establishment of men had existed until 1772, when a "corps of military artificers" was formed for service in Gibraltar, in place of the mixed lot of local civilians, soldiers and workmen from England. A similar organization for England was proposed in 1779; but prolonged discussion took place in parliament before a warrant was issued for the formation of six companies of military artificers, each consisting of 100 men, to be officered by the Royal Engineers. The companies were stationed in certain ports in the south of England and might not be employed elsewhere. This was the position during the greater part of the Napoleonic wars, and it is not surprising that Wellington's references to both artillery and engineers are often uncomplimentary. The whole of the train, artillery, engineers and stores departments being directly under the board of ordnance, were entirely independent of control by the military chiefs, while the board could never be persuaded to meet the demands of commanders in the field for either men or material. The numerous sieges in Spain were planned and conducted by engineer officers practically without technical troops or material. Their greatest privilege was to lead the storming party to the assault, where the majority met death or disablement. Wellington's chief engineer in the Peninsular War, Sir Richard Fletcher, was himself killed before San Sebastian in 1813. Four companies of Royal Sappers and Miners took part in this siege, Wellington's insistence having at last prevailed upon the board of ordnance to organize units of technical troops. In this same year the new name had been substituted for the old one of "military artificers." A regular organization was steadily built up, and at Waterloo in 1815 a brigade of engineers was attached to each division, and there was in addition a pontoon train of several companies. The French wars also led to certain improvements in the status and pay of senior engineer officers, and in 1802 the title of chief engineer in England was changed to "inspector-general of fortifications." Another result was the establishment in 1812 of the School of Military Engineering at Chatham under Capt. Charles Pasley, to give instruction to officers and men "in the duties of sapping and mining and other military field works." Pasley had been incapacitated by many wounds from further active service; he remained for nearly 30 years in control of the school, where his scientific knowledge, sane judgment, and broad vision left a permanent mark. The end of the French wars found the engineers at the summit of their fortunes, and the need for scientific soldiers had been proved to the utmost. The subsequent long peace brought drastic reductions and stagnation of promotion, till subalterns of 25 years' service became quite common. A slight improvement resulted from the inception of the ordnance survey of Ireland in 1825; and in 1832 the King granted to the corps its motto "Ubique quo fas et gloria ducunt." Little interest, however, was taken in military engineers until the Great Exhibition of 1851,

the construction of which was entrusted by the Prince Consort to Royal Engineer officers. The universality of application to engineering problems that they displayed, combined with the success of the exhibition, brought the corps prominently to notice; and the subsequent warm interest shown at all times by Queen Victoria opened the door to many and varied channels of scientific and general employment for R.E. officers. The opening of the Crimean War in 1854 found the engineers, like the rest of the army, reduced in numbers and starved for equipment. An immediate increase in numbers was made, seven battalions of sappers being formed, each battalion having 48 officers of Royal Engineers. The old defects in organization still persisted, and were only remedied as the result of the lessons of this war. In 1855 Lord Raglan, master general of the ordnance, died in the Crimea, and the whole board of ordnance was then abolished. Engineer officers and men were at last amalgamated in one "Corps of Royal Engineers" and came directly under the commander-in-chief.

The most distinguished engineer officer of this period, and the first engineer to become field-marshal, was Sir John Burgoyne, who won fame both as military and civil engineer; he died in 1871, aged 89 years, of which 68 had been devoted to the public service. The first mounted troop was hurriedly formed for the transport of bridging equipment in the Crimea, but had no regular status until 1863, when "A" pontoon troop and "B" field equipment troop were formed at Aldershot with a mounted depot to serve both. Field signalling had been first devised and practised at Chatham; also trials with the electric telegraph. Two sappers trained in telegraphy were sent to the Crimea, where they established precarious communication between the trenches and the base; but economy hampered progress, and little more was done until 1870 when, under the influence of the Franco-German War, "C" telegraph troop was added to those at Aldershot. In the same year a detachment of R.E. telegraphists was sent to the post office for employment and training; later they were formed into a regular unit, which for many years exercised complete control over the civil telegraph system in a large part of southern England. The mounted detachment (later named field troop, and then field squadron) was first formed for service in Egypt in 1885.

Ballooning for military purposes was first practised by the French revolutionary armies at the end of the 18th century. Early efforts by R.E. officers met with cold support, and not till 1890 was a proper establishment formed at Aldershot; theoretical instruction in ballooning being added at the same time to the Chatham course. The balloon detachment saw service in the Sudan in 1884, and later in Bechuanaland and South Africa; and gradually died out with the advance of aviation. Submarine mining was introduced by the Royal Engineers. Established as a regular service about 1863, it remained in the hands of the corps for more than 40 years, and was then taken over by the navy. Mechanical transport was another child of the military engineer. Instruction in the maintenance and driving of steam road vehicles (then termed steam "sappers") was given at Chatham, and the first steam road transport unit was organized for service in South Africa in 1899 as an engineer unit.

The charge of military buildings was entrusted to the Royal Engineers in 1826, and at the same time training in practical architecture was added to the course at the School of Military Engineering, Chatham. For over 100 years this has provided the principal means by which British military engineers have been practised in peace in the various branches of constructional engineering and have been kept abreast of scientific advance and development. The greatest monuments to their skill as architects are perhaps to be found in India, exemplified in the irrigation works, railways, surveys, roads, bridges, public buildings and defences of the country. The Indian corps of engineers, at first separately constituted in the three presidencies, and reorganized in 1770 by the East India Company, was finally amalgamated with and became part of the Corps of Royal Engineers in 1862, when Indian administration was transferred to the Crown.

During the latter half of the 19th century R.E. officers were prominent in many lands and many spheres as soldiers, scientists and statesmen. Among famous soldiers may be mentioned Field-Marshals Lord Napier, Sir J. Lintorn Simmons, Lord Nicholson and Maj.-Gen. Charles ("Chinese") Gordon. One of the outstanding figures of the World War of 1914–18, Field-Marshal Earl Kitchener, belonged to the corps of Royal Engineers, among whose officers many rose in the war to high commands and posts, the latter including both adjutant-general and quartermaster-general to the forces. The Institution of Royal Engineers was founded in 1875 with the object of "the general advancement of military science and more particularly for promoting the acquisition of historical and scientific knowledge in relation to engineering as applied to military purposes." In 1923 the institution received the honour of incorporation by royal charter.

United States.—*See* below.

France.—The history of the French engineers shows a somewhat similar development to that of the British. Originally, selected infantry officers were given brevets as engineers; they performed both civil and military duties for the king's service by the aid of companies of workmen, who were enlisted and discharged from time to time. The "Corps de Génie" was founded about 1690 by Vauban, a famous engineer known alike for his skill in designing fortresses and for his system of attack whereby many were later captured in far less time than had been expended in their building. Officers were selected from both soldiers and civilians for the corps, which soon achieved a world-wide reputation as the leading school of fortification and siege-craft. The title of "Génie" was conferred on officers in 1766 and on the companies of sappers and miners in 1801. The commander-in-chief of the French armies in 1914, Marshal Joffre, was an officer of the "Corps de Génie."

Germany.—Prior to 1809 there were separate corps of engineer officers, troops of miners, sappers and pontoniers. The disastrous campaign of 1806 led to reorganization of the army, and in 1809 the engineer troops were combined in a composite corps of engineers and pioneers. The corps was strictly relegated to building and fortress work, and had little if any share in the technical developments of the age. Although the staff took steps to ensure military control of systems of communication in war, military engineers had no part in the technical working of railways or telegraphs; thus they got gradually out of touch with tactics and military science generally. As a result of the Danish and Austrian wars, the higher control of pioneers and fortresses was reorganized, and engineer officers were given rather better opportunities to qualify for the command of all arms. Various improvements in organization had been completed when the Franco-German War of 1870 broke out; but there was a great shortage of officers and material which was continually felt in spite of the devoted service of the corps. There was also serious lack of mutual understanding between the pioneers and other arms. At this period a pioneer battalion consisted of three field companies, a pontoon column, train section, three fortress companies and a depot company. After the war many technical developments had to be pursued, but the corps always had to struggle for adequate establishments. Ballooning was investigated by the engineer committee in 1868. In 1870 two war balloons were obtained from England, and detachments were trained at Cologne to man them, but they met with little success. After the Franco-German war experiments were pushed ahead, and the balloon detachment was on a firm basis a few years later. Submarine mining was studied to some extent by engineer officers from 1871 onwards, but in 1884 was taken over finally by the navy.

THE WORLD WAR

General.—The War of 1914–18 has often been termed an engineers' war, a true description in so far that the increase in the engineer arm was proportionately much greater than in any other; but in the wider sense—the substitution of mechanical for human energy—field engineering made strangely little advance. The variety of work undertaken by military engineers and the numbers of men employed were alike immense. In the British army, on the outbreak of war, the engineer arm amounted to 2% of the total forces; in 1918 it had increased to 12% or 16% if the transportation branch is included; during the same period the total

engineer strength rose from under 14,000 to nearly 330,000. Tactical features varied from trench warfare, recalling the ancient art of siege-craft, to the most rapid movement of mobile columns; climatic conditions from the Arctic cold of Russia to the tropical heat of East Africa; while the enormous concentrations of men and material required, from engineers on lines of communication and at bases, constructional work on a scale previously unknown in war. The undoubted success of the British engineers in meeting these heavy demands is a testimonial to the basic soundness of their all-round training and elastic organization.

The heavy drain on French man-power in the early stages of the struggle made increases in the technical arms a matter of continuous difficulty, while serious drawbacks were inseparable from the system of entrusting rearward services to unfit and over-age personnel.

Engineer development in the German army followed much the same lines as in the British. The German engineers were always struggling to overcome the handicap of short numbers and lack of mutual understanding with which they started the war. They had constant difficulty in finding men for new scientific activities, and were further hampered by having to provide personnel to man the trench-mortar detachments which they initiated and kept throughout the war.

In the allocation of troops to the American army, based on the lessons of experience, provision for technical services was made on a far more liberal scale than had been found possible by any other nation.

Expansion and Work of the Royal Engineers.—Engineer units with the original expeditionary force consisted of a field squadron with the cavalry, one signal and two field companies per infantry division, one bridging train per corps, miscellaneous headquarters' signal units, and three small works or fortress companies for the base. Very early a third field company was added to each division; also an infantry pioneer battalion. Fortress companies were reorganized and re-named "army troops companies"; they undertook all general field engineering outside divisional zones and were raised on a scale of one per division with additions for lines of communication. By degrees various special units were formed both for the field armies and the bases, including electrical and mechanical, workshop, stores, land drainage, water supply, etc. Special tunnelling companies, composed of miners from the colliery districts, were raised early in 1915. By the end of 1916 there were, including men from the Dominions, 25,000 in the field. The greatest mining operation in military history was carried out in connection with the capture of the Messines ridge in June 1917, when charges containing nearly a million pounds of explosive were fired under the German lines. Water supply necessitated work of great importance and variety. Before the battle of the Somme 110 power pumps and 120m. of 4in. pipe-line were installed, and were then added to as the battle progressed. In Flanders special purification processes were largely used; from one pumping station alone 200,000 gallons of very impure Yser water were daily delivered, filtered and purified, to the troops. Special boring sections were formed for the chalk country, and deep well bores varying from 200ft. to 700ft. were sunk on the advice of geologists. For the Palestine campaign a pipe-line was laid across the desert, and filtered Nile water was delivered to a distance of over 150m. during the operations which drove the Turkish army from Beersheba. During the final three months of the war in France 326 steel girder bridges were erected by British and Dominion engineers, in addition to large numbers of timber and of pontoon equipment. Stock girders had been specially designed and details of erection carefully worked out during the long period of immobility; a number of spans were capable of carrying weights up to 30 tons, a striking increase over the pre-war normal load of two tons.

Miscellaneous duties of the engineers included camouflage, anti-aircraft searchlights, survey (including flash-spotting and sound-ranging), chemical warfare, meteorology, geology, post office. Tanks, although organized as a separate arm, were commanded, from their first introduction in 1916 to the end of the war, by a Royal Engineer officer. The part played by officers of the Royal Engineers in their conception and introduction is discussed under TANKS. A separate transportation branch was formed at the end of 1916 which assumed entire control of railways, normal and light, roads, inland water transport, cross-channel ferry, port construction, dock working, ropeways, and all the stores, workshops and administrative services concerned. Signal units remained part of the corps of Royal Engineers throughout the war, but formed practically an independent service. Faced with a multitude of new problems they underwent continual changes and expansion. During the first year of war 20,000m. of field cable were laid; and, during the final year, the amount was 245,000m., these figures being for France. The director of works at the base was responsible for engineering activities on a very great scale. Starting with but two assistants he controlled at the time of the Armistice a staff of nearly 200, in spite of having handed over forestry and engineer stores to independent directorates, and quarries to the transportation branch. Engineer stores were remarkable both for number and variety. A small proportion was procured in theatres of war by local purchase or production, but the main supplies were arranged for by the director of fortifications and works at the War Office. Varying from sandbags to complete irrigation plant for Mesopotamia the monthly shipping tonnage several times exceeded 200,000 tons. Of sandbags 313 million were despatched in one year, and 40 million in one month alone to France.

POST-WAR ORGANIZATION

British Army.—In the regular army the principal changes have been: the separation of signals from the Royal Engineers; the addition of a small headquarters unit, termed field park company, to divisional engineers; and the formation of an anti-aircraft searchlights engineer battalion. Other units that were found necessary in the war have since been provided as "supplementary reserve." They include transportation, army troops, electrical and mechanical, workshops and stores companies, bridging trains and postal section. The personnel of these units do short periods of training and receive a bounty, in return for which they accept liability to be called up for service in case of war. The territorial army embraces divisional, fortress and anti-aircraft searchlight engineers. Royal Engineers serving in India are organized in military engineer services and three corps of sappers and miners under the direct control of the engineer-in-chief; officers are also regularly employed under the civil departments of railways, surveys and public works. In the forces of the Dominions appropriate engineer troops are provided on a similar basis to the regular army. The total engineer strength of the regular army is roughly 1,100 officers and 7,700 other ranks. The latter include men of some two dozen different trades and are obtained partly by direct enlistment and partly from boys who are given a trade training before being posted to the ranks. The majority of the officers pass through the Royal Military Academy, Woolwich, as cadets, and then do a technical course of general and military engineering partly at the School of Military Engineering, Chatham, and partly at Cambridge university, where they study for the Mechanical Sciences Tripos. A few with engineering qualifications are admitted each year direct from the universities and the Dominions. Selected officers later go through practical courses in railway, electrical and mechanical engineering.

Other Armies.—The peace strength of the United States corps of engineers is about 350 officers and 5,000 other ranks. There is a separate signals service which, as in the case of the British army, has a strength roughly equal to half that of the engineers. Most armies now have a separate signals service, though it still has some connection with the engineer organization in the French, Italian, Japanese and Czechoslovak armies. In the last-named the bridging battalion is a special unit in which service is much sought after. Stationed on the Danube for the river defence of the republic it is quasi-naval, manning river gun-boats and performing mining and mine-sweeping duties, in addition to all forms of bridging. The Italian engineers are entrusted with a particularly wide range of duties. They have always been famous for their skill in overcoming the natural difficulties of mountainous

terrain and fast flowing rivers.

A camouflage section is now generally included among engineer troops. Searchlights form, in most cases, a function of the artillery, and this branch has taken over considerable survey activities, including flash-spotting and sound-ranging. The organization of the German engineer and pioneer corps, as defined by the Treaty of Versailles, remains practically as in 1914. The progress of "Mechanization" has peculiar interest for military engineers; and it is impossible to forecast the extent to which it may affect their future organization and employment. (G. H. A.)

UNITED STATES

The need for military engineers was recognized in the War of the Revolution, and General Washington was authorized to raise, officer and equip a corps of engineers. Three companies of sappers and miners were organized, and Brigadier General Louis LeBègue du Portail, of the Royal Corps of Engineers of the French Army, was made commandant of the corps. The appointment of a foreigner to fill this important post is indicative of the deficiency of trained engineering talent available at that time in the American states. The corps was mustered out of the service at the close of the war.

A corps of combined artillerists and engineers had a brief existence, commencing in 1794, but the disadvantage of uniting under one head the art of fortification and the service of artillery was soon apparent and the union was discontinued by the Act of Congress of March 16, 1802, which formally established the Corps of Engineers. The latter corps has constituted the principal engineer component of the regular army of the United States ever since. Officers with the special functions of topographical engineers were appointed on the staff during the War of 1812, and later were formed into a topographical bureau under the Chief of Engineers. A distinct Corps of Topographical Engineers, created in 1838, was merged into the Corps of Engineers in 1863. The Act of 1802 provided that the Corps should be stationed at West Point in the State of New York, where it should constitute a Military Academy, and that the officers should be available for duties elsewhere at the discretion of the President. Major Jonathan Williams was the first Superintendent of the Military Academy, the supervision of which remained in the hands of the Corps of Engineers until 1866, when the superintendency passed to the Army at large.

From the first the officers of the Corps were employed upon the fortification of the coast. For a long time they were the only trained engineers in the country, and their services were utilized on many important public works. Almost all of the routes of internal communication now in existence in the United States were first explored, located and projected by them. The non-military duties imposed upon the officers of the Corps of Engineers by various laws enacted from time to time by Congress embrace, to mention only a few: the improvement of the rivers and harbours of the country for commerce; the planning and construction of lighthouses and other fixed aids to navigation; the planning and construction of many public buildings, monuments and utilities in the National Capital, notably the Capitol, the Washington Monument, the Library of Congress and the Lincoln Memorial; the construction of the Panama Canal; the improvement of the Great Lakes for navigation; the opening of roads and trails in Alaska; and the enforcement of certain laws pertaining to water power and navigation.

Justification for employing army engineers in these civil peacetime pursuits is found in the opportunities such service affords for developing the engineering skill, broad experience in affairs, and general knowledge of the country, which are so valuable in an officer in time of war, whether in the handling of large bodies of troops in military engineering operations, or in the staff work of procurement of supplies, or in the application of the latest developments of engineering science to the solution of the problems arising out of new forms of warfare. The soundness of this policy has been repeatedly demonstrated, notwithstanding the view held by some officers that long periods of service on civil work tend to take officers out of touch with military progress. Whatever merit this contention may have had in the past, the statutory requirement that every officer shall serve with troops at least one year in every five largely corrects the tendency. Furthermore, it is now customary to give officers on civil assignment additional duties of a military nature, such as the conduct of military instruction for the officers of the Organized Reserves, thus ensuring that they keep abreast of changes in the tactics and technique of engineer troops. Officers of the Corps of Engineers have invariably been called upon to direct the creation and early pioneering of new branches of the military service. The submarine mine service, air service, chemical warfare service, the motor transport corps and the tank corps are examples. The Act of 1802, establishing the Corps of Engineers, made no provision for enlisting engineer troops and none were raised until 1812, when one company of bombardiers, sappers and miners was authorized for service in the war with Great Britain. After this company was disbanded in 1821, the army was without engineer troops until 1846 when a single company was again provided for service in the Mexican War.

Upon the outbreak of the Civil War in 1861 the number of engineer companies was increased to four, and, while no battalion organization was legally authorized, it was found expedient to form the companies into a provisional battalion to be commanded by the senior officer present. The battalion was attached to the Army of the Potomac during the winter of 1861–62, and was engaged chiefly upon the defences of Washington and in training. In the succeeding years of the war the battalion was engaged upon the construction of roads, fortifications, and bridges, with the troops in campaign. A noteworthy bridge constructed by this battalion was a pontoon bridge 1,980 feet long, built across the Chickahominy River on August 14, 1862.

The present army regulations charge the Corps of Engineers with the following duties within the theatre of operations: (1) All work of construction and the repair and maintenance of all structures of every character, except telephone and telegraph systems and other signal communications for the use of troops. (2) Military mining, demolitions and protective measures against enemy mines. (3) The operation of railways, portable and fixed electric light and power systems, water supply systems, and all other utilities of general service, except such as are specifically assigned to other services. (4) The execution of surveying and mapping, including the production and distribution of maps. (5) The procurement, storage and issue of all materials for construction work, for the organization of defence systems, and for all other operations assigned to the engineer service, including all plants, tools and appliances for such work.

These duties include: the construction, repair and maintenance of roads and trails; of bridges and other means for crossing rivers and similar obstacles; of shelter for troops and animals, including huts, hospital buildings, barracks, stables and accessory structures; of storehouses, shop structures, hangars and flying fields, including in proper cases the installation of the necessary machinery; of wharves, railroads and light railroads; the provision of water supply, including sterilization in bulk, the provision and installation of baths, disinfectors, dipping vats and incinerators; the installation of plumbing, sewage disposal and heating plants; the installation of machinery for refrigerating plants, laundries and other mechanical plants; assistance to other arms in entrenching, and in organizing defensive lines; the organization and construction of rear lines of defence; the construction of bombproofs, observation stations, machine-gun emplacements and other special works of defence; the execution of special measures for destroying or overcoming enemy obstacles; the supply of camouflage material and the supervision and inspection of its use; the preparation of signs for the direction of troops, including road signs, traffic signs, signs indicating the location of water points and other establishments, and signs safeguarding against the use of impure water; the operation of electric light, gas and power plants and water supply plants; the operation of shops for the erection and repair of railroad rolling stock, of construction machinery of all kinds and for the manufacture of special appliances for engineer operations; photographic and cinematographic work pertaining to terrestrial reconnaissance; terrestrial

surveying; map making and map reproduction; the training of engineer troops for all their duties, and the compilation of technical data and the preparation of training literature on subjects pertaining to any of the operations assigned to the Corps of Engineers.

The experience of the World War indicates that, to carry out these manifold duties, a proper proportion of engineer troops of all classes must be included with each field force if the combatant arms are to be free to devote their efforts to defeating the enemy, unembarrassed by diversions of fighting troops to tasks, no less essential, on the lines of communication. A field force containing an adequate proportion of supporting line-of-communication troops is called a "balanced force," and includes for each field army of 9 infantry divisions (approximately 400,000 troops) the following engineers:

Number of units required for balanced force	Type of unit	Unit strength	
		Officers	Enlisted men
9	Combat Regiments	38	845
10	General Service Regiments	38	1150
21	Engineer Battalions	16	1037
4	Bridge Battalions (heavy)	16	451
1	Camouflage Battalion	22	560
2	Mounted Battalions	15	330
6	Railway Battalions	18	622
1	Topographic Battalion (Army)	18	560
1	Topographic Battalion (GHQ)	18	560
2	Water Supply Battalions	18	590
6	Bridge Companies (light)	4	160
1	Camouflage Company	13	250
5	Depot Companies	4	160
2	Dump Truck Companies	4	152
2	Railway Shop Companies	4	160
2	Shop Companies	4	160
2	Railway Headquarters	10	27
	Engineer sections at		
1	General Headquarters	9	26
1	General Headquarters Reserve	9	23
1	Communications Zone	10	27
1	Army Headquarters	28	105
3	Corps Headquarters	5	17

The combat and general service regiments, mounted battalions, and engineer battalions, are denominated general engineer troops; all others are special engineer troops. General engineer troop units which constitute 70% of the engineers in a balanced force differ among themselves principally in size and in the qualifications of the headquarters personnel.

The special engineer organizations are provided for purposes suggested by their names. Bridge battalions and companies transport the equipage with which general engineer troops construct floating bridges. Camouflage battalions manufacture and supply camouflage materials and give instructions to troops in their proper employment. Railway battalions operate and maintain railways, both narrow and broad gauge. Topographic battalions make terrestrial surveys and reproduce maps by photolithographic processes. Water supply battalions transport water in tank trucks. Depot companies furnish the technical personnel for engineer supply establishments. Dump truck companies furnish transportation on engineer operations involving earthwork. Railway shop companies make major repairs to standard railway equipment. Shop companies assemble, test and repair machinery and do manufacturing.

Most engineer units are armed and trained to engage in combat as riflemen, but, except for a few automatic rifles with the combat and general service regiments, and machine guns with the mounted battalions, the units lack the supporting weapons and communication equipment requisite to effective infantry combat. It is only the gravest emergency that warrants the employment of the highly trained technical personnel of engineer units in combat, as such use involves the virtual abandonment of maintenance work on the routes of communication, and must ultimately result in the breakdown of supply and the curtailment of manoeuvre. The chief engineer officer at each headquarters is known as the unit engineer. He has the dual role of technical staff officer and commander of engineer troops. In the infantry and cavalry divisions the commander of the divisional engineer troops is a member of the staff of the division commander.

During the World War there was a tendency toward over-specialization in engineer troop units, separate organizations being raised for many special purposes besides those outlined above. The consensus of military thought is that the most satisfactory results can be obtained when the bulk of the engineer service consists of general engineer units. These are so organized, equipped and trained, that they may be employed indiscriminately upon engineer work of almost any character, whereas special units, being recruited usually from a limited class of artisans and being organized and equipped for particular purposes, are not readily adaptable to employment upon tasks not closely related to their specialties.

Most of the officers of the Corps of Engineers are obtained from the United States Military Academy at West Point, a few cadets at the head of each class being selected for assignment to the corps. In addition, a few officers are obtained from the graduates of civil technical schools. The education of the engineer officer continues throughout his career in the Army. Those officers who graduate from West Point are sent for one year to civil institutions to supplement their instruction in technical subjects not included in the curriculum of the Military Academy. All the officers, including those from West Point, attend for one year the Engineer School at Fort Humphreys, Virginia, where they pursue the Company Officers' Course, covering military engineering, harbour defence, tactics, logistics and certain engineering subjects pertaining to the civil work of the corps. The next step in the educational scheme is detail as student officers under district engineer officers engaged on civil works, after which the officers are available for general assignment. Engineer officers, like other army officers, are subject to further military education at the Command and General Staff School, at the Army Industrial College, and at the Army War College. It is the policy of the Chief of Engineers to broaden the officers' knowledge of the country by assigning them to duty in different localities. It will be seen from the foregoing that no effort is made to develop specialists, although, through necessity, some officers must be dedicated to such specialties as aerial photographic mapping, map reproduction and certain hydraulic technicalities incident to the civil work of the Corps. The aim is rather to give a broad and general scientific and practical training, looking ultimately to the application of physical science to the preparation for and conduct of military operations. A school for the instruction of enlisted specialists is conducted at Fort Humphreys. Practical experience is given selected men in suitably equipped shops in map reproduction, photography, mechanical drafting, surveying and machinery.

The training of the officers of the Corps of Engineers reserve comprises correspondence courses, inactive duty conference courses and fifteen-day periods of active duty training either with troops of the Regular Army or at headquarters, depending upon their individual assignments. A limited number of reserve officers attend the Engineer school.

When the United States entered the World War, the engineers available for immediate service consisted of 256 officers and 2,228 soldiers. At the time of the Armistice in November, 1918, there were under the Corps of Engineers 10,886 engineer officers and 292,300 soldiers of whom 174,000 (officers and men) were with the American Expeditionary Forces. The Engineers with the American Expeditionary Forces, besides participating in all combat operations, handled over 3,000,000 tons of engineer supplies, constructed an aggregate of 6,360 feet of wharves at ports, constructed 967 miles of standard gauge railroad, provided hospital space for 141,000 beds, constructed 16,000 barracks, operated 1,390 miles of light railway and cut 218,211,000 board feet of lumber.

As now organized (1928), the engineer branch of the army of the United States includes the Corps of Engineers of the Regular Army, 520 officers and about 5,000 enlisted men; the engineer organizations of the National Guard, about 500 officers and 8,000 enlisted men; and the engineer section of the Officers' Reserve Corps, about 7,000 officers. The latter are given assignments to organizations which are to be mobilized in time of war, but which are without enlisted men in peace time. (G. B. T.)

ENGINES OF WAR. The bow was in all probability the earliest "engine" of war devised by man, the sling and the blowpipe being of later date. In any case we know that the bow was used in the South of France and Cantabria by the prehistoric hunter-artists in the 10th millennium B.C., and that in the East from the earliest historical times it was a common weapon of war. The idea of a more powerful weapon, especially in siege work, when it was necessary to outrange the hand bow in order to cover by fire the approach of scaling and assaulting parties, probably arose in the East during the 9th or 8th century B.C. In the Bible we read that Uzziah, who reigned from 808–9 to 756–7 B.C., "made in Jerusalem engines invented by cunning men, to be on the towers and upon the bulwarks, to shoot arrows and great stones withal."

These engines fall into two main groups, namely, catapults (*q.v.*) and ballistae which to-day are represented by howitzers and guns, the first being used for high and the second for low trajectory fire. In both cases the force of propulsion was generated by tightly twisting a skein of rope, hair or sinew, prepared in a manner now unknown, for though in recent years many replicas of both these engines have been constructed the problem of maintaining the elasticity of the sinews has remained unsolved. Nevertheless, sufficient experience has been gained with the indifferent modern machines to prove that the range claimed by classical writers, varying from 400 to 800 yards, is no exaggeration. The projectiles used were of various kinds, such as large arrows, small metal balls, stone balls and large pebbles coated in baked clay which shattering on impact prevented the enemy using them in his own machines. Their weight varied from a few pounds to sixty or even more. The most complete account of the catapult is given by the historian Ammianus Marcellinus, who says: "In the middle of the ropes (twisted skein) rises a wooden arm like a chariot pole . . . to the top of the arm hangs a sling . . . when battle is commenced a round stone is set in the sling . . . four soldiers on each side of the engine wind the arm down till it is almost level with the ground . . . when the arm is set free it springs up and hurls forth from its sling the stone, which is certain to crush whatever it strikes. This engine was formerly called the 'scorpion,' because it has its sting erect, but later ages have given it the name of onager, or wild ass, for when wild asses are chased they kick the stones behind them." As a protection against the projectiles thrown, Caesar informs us that curtains woven from cable-ropes were sometimes used.

The origins of artillery among the Greeks probably took place in Sicily where they came into contact with the Carthaginians. Diodorus informs us that engines first came into use in 397 B.C. when Dionysius of Syracuse was waging his Punic War. In any case at a later date the Carthaginians relied very largely on artillery. We learn from Livy that when New Carthage was taken by the Romans in 146 B.C., 120 great catapults, 281 small ones, 23 great ballistae and 52 small ones were captured. And it may be noted, that according to Appian of Alexandria, a little previous to this siege the Carthaginians surrendered to the Romans "catapults for shooting swift bolts and for throwing stones to the number of 2,000."

It appears that from Sicily these machines were introduced into Greece, for they were certainly made use of by Philip of Macedon, 360–336 B.C. Under his son Alexander a definite body of artillerists was established, ballistae being mounted on carriages, known later as carro-ballistae, and used by this great soldier as field and mountain artillery are to-day, especially in his campaigns against the Danube tribes and the Scythians. Under his successors, the Diadochi, it may be said that an artillery age was entered, for not only do we find a frequent use of catapults and ballistae but an ever increasing interest taken in their construction by the scientists of Alexandria. There, in the 3rd century B.C., a certain Dionysius invented the first recorded machine-gun called "polybolos" or "repeater-thrower," which fired a succession of arrows from a magazine. At about the same time Ctesibius, an Alexandrian engineer, geared to the catapult arms pistons "working in carefully wrought cylinders." Accounts of these engines and others are given in the works of Heron (284–221 B.C.) and Philo (about 200 B.C.). Among the successors of Alexander, the greatest engineer was undoubtedly the famous Demetrius Poliorcetes, who in 304 B.C. besieged Rhodes, and used all manner of projectile engines, and so important did they become in field and siege operations that at the third battle of Mantineia (207 B.C.) we find a counterpart to the modern artillery battle (*see* Polyb. xi. 12).

In their turn the Romans copied the Greeks, but produced less perfect weapons, such as those depicted on the Trajan Column. The Romans made frequent use of them, having learnt to their cost their value during their siege of Syracuse in 214–212 B.C., in which siege, as Plutarch tells us in his Life of Marcellus, Archimedes "was the informing soul. All other weapons lay idle and unemployed, his were the only offensive and defensive arms of the city." Further Plutarch writes: "Archimedes soon began to play his engines upon the Romans and their ships, and shot stones of such an enormous size (about 100 lb.) and with so incredible a noise and velocity that nothing could stand before them. The stones overturned and crushed whatever came in their way, and spread terrible disorder through the Roman ranks. . . . At length the Romans were so terrified that, if they saw but a rope or a beam projecting over the walls of Syracuse, they cried out that Archimedes was levelling some machine at them and turned their backs and fled."

From this date onwards we find the Romans paying more and more attention to artillery, and especially so in the first century B.C. In the days of Julius Caesar full use was made of catapults and ballistae in the field as is illustrated by his battle with the Bellovaci in 51 B.C., when he drew up his engines in such a way that they could play upon the enemy's columns. At Dyrrachium his IXth Legion seized a hill and began to fortify it when Pompey's soldiers occupied a neighbouring hill and brought such a concentrated artillery fire to bear on Caesar's legionaries that they were forced to withdraw. Josephus, an eyewitness, informs us that at the siege of Jotapata, in A.D. 67, Vespasian used 160 engines. He says: "The noise of the instruments themselves was very terrible, the sound of the darts and stones that were thrown by them was so also; of the same sort was the noise that dead bodies made when they were dashed against the wall." From about this date onwards artillery became an established arm in the legion, and according to Vegetius each cohort was equipped with one catapult, and each century with one carro-ballista, 11 soldiers being required to work the latter machine. The legion, therefore, possessed an artillery train of 60 carro-ballistae and ten catapults, 70 engines in all, which corresponds closely to the number of field-guns and howitzers in a modern infantry division. *See* CATAPULT, BATTERING RAM, FORTIFICATION AND SIEGECRAFT.

BIBLIOGRAPHY.—The works of Ammianus Marcellinus; Arrian; Appian; Julius Caesar; Diodorus; Josephus; Plutarch; Polybius; Procopius; Tacitus; Vegetius and Vitruvius. An invaluable book is *Mathematici Véteres* by Melchisedech Thévenot (1620–92, republished by C. Wescher, Paris, 1869). It contains the works of Apollodorus of Damascus; Athenaeus, a contemporary of Archimedes; Biton; Heron of Alexandria and Philo of Byzantium. ENGIS, a cave on the banks of the Meuse near Liége, Belgium, where in 1832 Dr. P. C. Schmerling found human remains in deposits belonging to the Quaternary period. Bones of the cave-bear, mammoth, rhinoceros and hyena were discovered in

association with parts of a man's skeleton and a human skull. This, known as "the Engis Skull," gave rise to much discussion among anthropologists, since it has characteristics of both high and low development.

See P. C. Schmerling, ***Recherches sur les ossements découverts dans les cavernes de la province Liège*** (1833); Huxley, ***Man's Place in Nature***, p. 156; Lord Avebury, ***Prehistoric Times***, p. 317 (1900).

ENGLAND. Geographical usage confines the name to the southern part of the island of Great Britain, excluding its western peninsula of Wales. It is the largest, wealthiest and most populous of the units within the United Kingdom of Great Britain and Northern Ireland.

England extends from the mouth of the Tweed in 55° 46′ N. to Lizard Point in 49° 57′ 30″ N., in a roughly triangular form. The base of the triangle runs from the South Foreland to Land's End west by south, a distance of 316 m. in a straight line, but 545 m. following the larger curves of the coast. The east coast runs north-north-west from the South Foreland to Berwick, a distance of 348 m., or, following the coast, 640 m. The west coast runs north-north-east from Land's End to the head of Solway Firth, a distance of 354 m., or following the much-indented coast, 1,225 m. The total length of the coast-line may be put down as approximately 2,350 m., out of which 515 m. belong to the western principality of Wales. The most easterly point is at Lowestoft, 1° 46′ E., the most westerly is Land's End, in 5° 43′ W. The coasts are nowhere washed directly by the ocean, except in the extreme south-west; the south coast faces the English Channel, which is bounded on the southern side by the coast of France, the two shores converging from 100 m. apart at the Lizard to 21 at Dover. The east coast faces the shallow North sea, which widens from the point where it joins the Channel to 375 m. off the mouth of the Tweed, the opposite shores being occupied in succession by France, Belgium, Holland, Germany and Denmark. The west coast faces the Irish sea and St. George's Channel, with a width varying from 45 to 130 m.

The area of England and Wales is 37,327,479 ac. or 58,324 sq.m. (England, 50,851 sq.m.). The principal territorial divisions of England, as of Wales, Scotland and Ireland, are the counties (*see* below), of which England comprises 40. Their boundaries are not always determined by the physical features of the land; but localities are habitually defined by the use of their names.

Physical Geography.—The land is highest in the west and north, where the rocks also are oldest, most disturbed, and hardest, and the land surface gradually sinks towards the east and south, where the rocks become successively less disturbed, more recent and softer. The study of orographical and geological maps of the country allows a broad distinction to be drawn between the west and east. The contrasted districts are separated by an intermediate area, which softens the transition between them, and may be described separately.

The Western Area is composed of Archaean and Palaeozoic rocks, embracing the whole range from pre-Cambrian up to Carboniferous. The outcrops of these rocks succeed each other in order of age in roughly concentric belts, with the Archaean mass of the island of Anglesey as a centre, but the arrangement in detail is much disturbed and often very irregular. Contemporary igneous outbursts are important in some of the ancient formations, and add, by their resistance to atmospheric erosion, to the ruggedness of the scenery (*see* CARNARVONSHIRE). The hills and uplands of ancient rocks do not always form regular ranges, but often rise like islands in distinct groups from a plain of New Red Sandstone (Permian and Triassic), which separates them from each other and from the newer rocks of the Eastern Area. Each of the uplands is a centre for the dispersal of streams that flow rapidly to the sea.

The Eastern Area, lying to the east of the zone of New Red Sandstone, is defined on the west by a slightly curved line drawn from the estuary of the Tees through Leicester and Stratford-on-Avon to the estuary of the Severn, and thence through Glastonbury to Sidmouth. It is built up of nearly uniform sheets of Mesozoic rock, the various beds of the Jurassic lying above the New Red Sandstone (Triassic), and dipping south-eastward under the successive beds of the Cretaceous system. In exactly the same way the whole of the south-east of the island appears to have been covered uniformly with gently dipping beds of early Tertiary sands and clays, beneath which the Cretaceous strata dipped. At some period subsequent to this deposition there was a movement of elevation, which appears to have thrown the whole mass of rocks into a fold along an anticlinal axis running west and east, which was flanked to north and south by synclinal hollows. In these hollows the early Tertiary rocks were protected from erosion, and remain to form the London and the Hampshire Basins respectively, while on the anticlinal axis the whole of the early Tertiary and the upper Cretaceous strata have been dissected away, giving the complex configuration of the Weald. The general character of the landscape in the Eastern Area is a succession of steep escarpments formed by the edges of the outcropping beds of harder rock, and long gentle slopes or plains on the dip-slopes, or on the softer layers; clay and hard rock alternating throughout the series.

The structural contrasts between the Western and the Eastern Areas are masked in many places by deposits of boulder clay, covering most of the low ground north of the Thames basin.

The history of the origin of the land-forms of England is exceedingly complicated. Every geological formation (except the Miocene) is represented, suggesting a long and complicated past. Geologically the separation of Ireland was a comparatively recent episode, while the severance of the land-connection between England and the continent by the formation of the Strait of Dover is still more recent and within the human period.

NATURAL DIVISIONS

The Western Area: The four groups of high land rising out of the plain of red rocks are:—

(*a*) The Lake district, bounded by the Solway Firth, Morecambe bay and the valleys of the Eden and the Lund.

(*b*) The Pennine region, which stretches from the Scottish border to the centre of England running south.

(*c*) Wales (*q.v.*), forming the western landward boundary of England.

(*d*) The South-western peninsula, comprising mainly the counties of Devon and Cornwall.

They are all similar in the great features of their land-forms, which have been impressed upon them by the prolonged action of atmospheric denudation rather than by the original order and arrangement of the rocks; but each group has its own geological character, which has imparted something of a distinctive individuality to the scenery. Taken as a whole, the Western Area depends for its prosperity on mineral products and manufactures rather than on farming; and the staple of the farmers is live-stock rather than agriculture.

Lake District.—The Lake District occupies the counties of Cumberland, Westmorland and north Lancashire. It forms a roughly circular highland area, the drainage lines of which radiate outward from the centre in a series of narrow valleys, the upper parts of which cut deeply into the mountains, and the lower widen into the surrounding plain. Many of the valleys have long narrow lake basins such as Windermere and Coniston, draining south; Wastwater, draining south-west, Ennerdale water, Buttermere and Crummock water (the two latter, originally one lake, are now divided by a lateral delta), draining north-west; Derwent water and Bassenthwaite water (which were probably originally one lake), and Thirlmere, draining north; Ullswater and Haweswater, draining north-east. There are, besides, numerous mountain tarns of small size, most of them in hollows barred by the glacial drift which covers a great part of the district. The central and most picturesque part of the district is formed of great masses of volcanic ashes and tuffs, with intrusions of basalts and granite, all of Ordovician (Lower Silurian) age. Scafell and Scafell Pike (3,162 and 3,210 ft.), at the head of Wastwater, and Helvellyn (3,118), at the head of Ullswater, are of great grandeur in spite of their moderate height. Sedimentary rocks of the same age form a belt to the north, and include Skiddaw (3,054ft.); while to the south a belt of Silurian rocks, thickly covered with boulder

clay, forms the finely wooded valleys of Coniston and Windermere. Round these central masses of early Palaeozoic rocks there is a broken ring of Carboniferous limestone, and several patches of Coal Measures, while the New Red Sandstone appears as a boundary belt outside the greater part of the district, and is especially marked in the vale of Eden and the Carlisle plain, giving good agricultural land. Where the Coal Measures reach the sea at Whitehaven, there are coal-mines, and the hematite of the Carboniferous limestones has given rise to ironworks at Barrow-in-Furness. Except in the towns of the outer border, the Lake district is very thinly peopled, although the remarkable beauty of its scenery attracts numerous residents and tourists. The very heavy rainfall of the district, which is the wettest in England, has led to the utilization of Thirlmere as a reservoir for the water supply of Manchester, over 80m. distant. The district is one of human contrasts, between the simple pastoral life of the high moorlands, and the richer agricultural life that centres around the "Border City," Carlisle. Both forms of life are in greater contrast to the industrial regions of the western coastland south of the district.

Pennine Region.—The Pennine region, the centre of which forms the so-called Pennine Chain, is the outstanding feature of northern England. The region is composed of Carboniferous rocks, the coal and iron deposits making the flanks of the highland busy manufacturing districts, and the centres of dense population. The whole region may be looked upon as formed by an arch or anticline of Carboniferous strata, the axis of which runs north and south; the centre has been worn away by erosion, so that the Coal Measures have been removed, and the underlying Millstone Grit and Carboniferous limestone exposed. On both sides of the arch, east and west, the Coal Measures form outcrops which disappear towards the sea under the more recent strata of Permian or Triassic age. The northern part of the western side of the anticline is broken off by a great fault in the valley of the Eden, and the scarp thus formed is rendered more abrupt by the presence of a sheet of intrusive basalt. In the north the Pennine region is joined to the Southern Uplands of Scotland by the Cheviot hills, a mass of granite and Old Red Sandstone; and the northern part is largely traversed by dykes of contemporary volcanic or intrusive rock. The most striking of these dykes is the Great Whin Sill, which crosses the country from a short distance south of Durham almost to the source of the Tees, near Crossfell. The elevated land is divided into three masses by depressions, which furnish ready means of communication between east and west. The South Tyne and Irthing valleys cut off the Cheviots on the north from the Crossfell section, which is also marked off on the south by the valleys of the Aire and Ribble from the Kinder Scout or Peak section. The numerous streams flow to the east and the south, and, by shorter and steeper valleys, to the west. The dales are separated from each other by high heather covered moorland or hill pasture. The agriculture of the region is confined to the bottoms of the dales, and is of small importance. Crossfell (2,930ft.) and the neighbouring hills are formed from masses of Carboniferous limestone, which received its popular name of Mountain limestone from this fact. Farther south, such summits as High Seat, Whernside, Bow Fell, Penyghent and many others, all over 2,000ft. in height, are capped by portions of the grits and sandstones, which rest upon the limestone. The belt of Millstone Grit south of the Aire, lying between the great coal-fields of the West Riding and Lancashire, has a lower elevation, and forms grassy uplands and dales; but farther south, the finest scenery of the whole region occurs in the limestones of Derbyshire, in which the range terminates. The limestone rocks of Yorkshire and Derbyshire show characteristic subterranean drainage. The coal-fields on the eastern side, from the Tyne nearly to the Trent, are sharply marked off on the east by the outcrop of Permian dolomite or Magnesian limestone, which forms a low terrace dipping towards the east under more recent rocks, and in many places giving rise to an escarpment facing westward towards the gentle slope of the Pennine dales. To the west and south the Coal Measures dip gently under the New Red Sandstone, to reappear at several points through the Triassic plain. The clear water of the upland becks and the plentiful supply of water-power led to the founding of small paper-mills in remote valleys before the days of steam.

The Pennine footlands in the north-east form a very distinct geographical unit, which may be termed North-eastern England. The region is bounded on the north-west by the Cheviots, on the west by the northern Pennines and on the south-east by the North Yorkshire moors. Three important lowland gates leave the region, namely the Northallerton gate to the south, the Tyne Gap to the west and the Berwick gate to the north. The region is one of great contrast between the highly developed, congested, industrial coastal patch and the sparsely populated, bleak, sheep-rearing moorlands of the Pennines to the west. Coal has been exported from this area for centuries and the association of boatbuilding for coal-carrying has laid the foundation of the great shipbuilding industry. The use first of all of local deposits of iron ore and then of the imported raw material has made the region also a great iron-smelting area. The great industries focus around the estuaries respectively of the Tyne, Wear and Tees. Coal, chemical products and shipbuilding focus on Newcastle-on-Tyne—the regional capital. Sunderland, the focus on the Wear, imports timber and exports coal. Difficulties in the early days with the lower Tees channel were overcome by sending the coal to Middlesbrough, where it met with the imported iron ores and thence arose a great iron-smelting region. The discovery of the Cleveland ores and new processes in smelting greatly improved the economic position of this region and now the iron-smelting and its associated industries are world famous. The development of the heavy chemical industry based on the gypsum deposits of the Triassic is a new development. The Tees-mouth ports are grouped under Middlesbrough, Stockton and the Hartlepools. Behind the whole region lies the old-world focus of Durham, beautifully situated—the one-time capital of a vast ecclesiastical border march.

Farther south the footlands of the Pennines have long been interested in woollen industries based upon sheep-rearing. The introduction of cotton caused the woollen manufactures on the western side to be superseded by the working up of the imported raw material; but woollen manufactures now based on imported raw materials have become a feature of the eastern slopes. Some quiet market-towns, such as Skipton and Keighley, remain, but most of them have developed by manufactures into great centres of population, lying, as a rule, at the junction of the thickly peopled valleys, and separated from one another by the empty uplands. Such are Leeds, Bradford, Sheffield, Huddersfield and Halifax on the great and densely-peopled West Riding coal-field, which lies on the eastern slope of the Pennines. The availability of soft water, from the Millstone Grit and peat moorlands, for wool-washing is an important factor of the location of wool-towns, in the main to the north of the Calder. The traditional skill of the inhabitants has also been an important factor in the location and development of the modern woollen industry and many of the towns within the region show a high degree of specialization. Thus Bradford specializes in wool-combing and worsted work; Dewsbury in "shoddy," or the reworked material; Halifax in carpet making and heavy woollens and the Colne valley in fine clothes and tweeds. Leeds is the mercantile and engineering centre of the district with, for example, a leather industry due to its large meat markets.

High on the Pennines are Harrogate, Buxton and Matlock, health resorts, prosperous from their pure air and fine scenery.

The iron ores of the Coal Measures have given rise to great manufactures of steel. This industry has focussed on Sheffield. Familiarity with the smelting of local iron ore and the proximity of hard sandstone for grinding wheels has handed on a traditional skill in this neighbourhood also. Before the extended use of coal, the local smelting was dwindling, but cutlery manufacture revived, thanks to imported iron. With the use of coal power the production of steel and its associated industries concentrated in the Don valley.

Across the moors, on the western side of the anticline, the vast and dense population of the Lancashire coal-field is crowded in the manufacturing towns surrounding the great commercial centre, Manchester, which itself stands on the edge of the Triassic plain.

Ashton, Oldham, Rochdale, Bury, Bolton and Wigan form a nearly confluent semicircle of great towns, dependent on the underlying coal and iron and on imported cotton. The lime-free water of the region is also important for bleaching. The Lancashire coal-field, and the portion of the bounding plain between it and the seaport of Liverpool, contain a population greater than that borne by any equal area in the country, the county of London and its surroundings not excepted. Here again the region shows concentration in certain towns of highly specialized processes. Bolton concentrates on the spinning of fine Egyptian cotton and is important in the bleaching industry; Oldham deals with the medium counts, while the suburbs of Manchester deal with spinning and the city itself is the great market of the finished goods. Liverpool stands out as the great entrepôt for raw cotton and the export centre of the finished goods.

Triassic rocks form the low coastal belt of Lancashire, edged with long stretches of blown sand and dotted with pleasure towns like Blackpool and Southport.

The basin of the River Weaver is the centre of the Cheshire salt-field. Modern developments tend to make this and the mid-Mersey region generally the producer of heavy chemical goods—a factor of no little importance in the bleaching processes.

Chester is the seaward terminus of the way through the great Midland Gap. Like Durham on the north, it was once of greater importance than at present, as the head of a marcher lordship, in this case controlling ways into Wales and the west. The importance of Chester in this region is that it has links with the south, the midlands and the west rather than with the north, but it has become of late a residential centre in relation to the south Lancashire cities, thanks to recent improvements of transport.

In the south-west of the Pennine region the coal-field of North Staffordshire supports the group towns known collectively from the staple of their trades as "the Potteries." The region is somewhat isolated industrially and is mainly dependent on the suitable carboniferous clays and marls. Six of the important pottery towns have been amalgamated into the county borough of Stoke-on-Trent which with extended boundaries was raised in 1925 to the rank of a city (Pop. 1921, 278,000). Further extension of this urbanization will accentuate the already too elongated nature of the settlement. The extreme contrast between Stoke and the non-industrial, old-world town of Newcastle-under-Lyme is one that repeats itself in many parts of modern England.

The South-west.—The peninsula of Cornwall and Devon may be looked upon as formed from a synclinal trough of Devonian rocks, which appear as plateaux on the north and south, while the centre is occupied by Lower Carboniferous strata at a lower level. The northern coast, bordering the Bristol channel, is steep, with picturesque cliffs and deep bays or short valleys running into the high land, each occupied by a little seaside town or village. The plateau culminates in the barren heathy upland of Exmoor, which slopes gently southward from a general elevation of 1,600 ft., and is sparsely inhabited. The Carboniferous rocks of the centre form a soil which produces rich pasture under the heavy rainfall and mild climate, forming a great cattle-raising district. There is an interesting seasonal migration of cattle and sheep up to Bodmin Moor and Dartmoor. The Devonian strata on the south do not form such lofty elevations as those on the north, and are in consequence, like the plain of Hereford, very fertile and peculiarly adapted for fruit-growing and cider-making. The remarkable features of the scenery of south Devon and Cornwall are due to a narrow band of metamorphic rock which appears in the south of the peninsulas terminating in Lizard Head and Start Point, and to huge masses of granite and other eruptive rocks which form a series of great bosses and dykes. The largest granite boss gives relief to the wild upland of Dartmoor, culminating in High Willhays and Yes Tor. The clay resulting from the weathering of the Dartmoor granite has formed marshes and peat bogs. The Tamar flows from north to south on the Devonian plain, which lies between Dartmoor on the east and the similar granitic boss of Bodmin Moor (where Brown Willy rises to 1,345 ft.) on the west. There are several smaller granite bosses, of which the mass of Land's End is the most important. Most of the Lizard peninsula, the only part of England stretching south of 50° N., is a mass of serpentine. The great variety of the rocks which meet the sea along the south of Cornwall and Devon has led to the formation of a singularly picturesque coast—the headlands being carved from the hardest igneous and metamorphic rocks, the bays cut back in the softer strata. The fjord-like inlets of Falmouth, Plymouth and Dartmouth are splendid natural harbours, which would have developed great commercial ports but for their remoteness from the centres of commerce and manufactures. China clay from the decomposing granites, tin and copper ore abound at the contacts between the granite and the rocks it pierced. The mineral wealth of the peninsula, especially its tin, attracted prospectors in early times, while mining has been one of the staples of Cornwall for centuries. Redruth and Camborne were the chief centres. Foreign competition and obsolete machinery brought about the collapse of the industry at the end of the 19th century, not before Cornish mining captains had become famous as metal prospectors the world over. The diminution of alluvial supplies of tin from abroad and the consequent rise in the market price, is tending (1928) to cause a revival of mining. Fishing has always been important, the numerous good harbours giving security to the fishing boats. The south-western end of the peninsula is fortunately situated near the southern limit of the cold-water herring and the northern limit of the warm-water pilchard. The sea-faring traditions of the south-west are based on the facilities it gave as a training ground. The Drake and Hawkins type are needed no more now and fishing is a precarious existence and it is with difficulty that the fishermen turn to other activities.

The mild and sunny, but by no means dry, coast has led to the establishment of many health resorts, of which Torquay is the chief. This traffic is increasing with the motor-car.

The peninsula of the south-west, in its isolation, has developed in its people a sense of individuality and aloofness from the life of the English plain. It has many claims to live on a long and glorious past of its own. Saxon colonization never extended west of the Tamar and the Cornish language of Celtic affinity became extinct only in the 18th century. Exeter, once the outpost of this old British kingdom, is now the administrative and ecclesiastical capital.

The Midland Plain.—Between the separate uplands just described, there extends a plain of Permian and Triassic rocks, which may conveniently be considered as an intermediate zone between the two main areas—the west and the east. To the eye it forms an almost continuous plain with the belt of Lias clays, which is the outer border of the Eastern Area; for although a low escarpment marks the line of junction, and seems to influence the direction of the main rivers, there is only one plain so far as regards free movement over its surface and the construction of canals, roads and railways. The plain usually forms a distinct border along the landward margins of the uplands of more ancient rock, though to the east of the Cornwall-Devon peninsula it is not very clear, and its continuity in other places is broken by inliers of the more ancient rocks, which everywhere underlie it.

In the north-west we find a tongue of red rocks forming the Eden valley with Carlisle as its centre, while farther south these rocks help to form the low coastal belt of Lancashire. Triassic rocks also form the Cheshire Plain to the south of the Lancashire coalfield. The plain extends through Staffordshire and Worcester and Hereford forming the lower valley of the Severn. The red soil is good for agriculture which is very well developed in these counties. Orchards and hop-growing are also important, particularly in Herefordshire. The flat surface and low level of much of this country has facilitated the construction of railways, canals and roads. Shrewsbury in its remarkable river loop was long a great fortress guarding ways into Wales and it remains a great market town to-day: it is also the centre of a considerable railway traffic. The great junction of Crewe is a further example of convergence of many routes on this lowland. The new and old red sandstone plains back against the Welsh plateau and there is a characteristic series of old towns beneath the hills where valleys open into the plain. Chester, Wrexham, Ruabon,

ENGLISH AND WELSH SCENERY

1. Chalk cliffs at Dover. The chalk country still extant in England is the northern edge of the great sheet of chalk which once covered the whole southeastern part of the island. The Dover cliffs are especially familiar, being the traveler's first view of England when crossing the English channel from Calais
2. View of Chagford, Dartmoor, from Meldon Hill, a characteristic moorland landscape. The elevation of this section of Devonshire is about 1,400 ft., with many higher hills. It is fertile pasture land. The moorland region as a whole is an excellent country for walking excursions, for which Chagford is frequently used as a base
3. Mullion cove on the coast of Cornwall, the southwestern spur of Great Britain. The Cornish coastline is rocky and forbidding, with numerous coves, once used as hiding-places for smugglers
4. The Waveney, one of the shallow streams in the district of the Norfolk Broads, on the east coast of England. A number of shallow lagoons with their connecting streams make this part of the country a favourite resort for angling and smooth-water sailing
5. The Lledr Valley, North Wales, with Moel Siabod in the distance. The valley is green and pastoral in the eastern part, but towards the west is rocky and much quarried

Chirk, Oswestry, Shrewsbury, Ludlow, Leominster and Hereford may be named here.

An outcrop of the Coal Measures from beneath the newer rocks increases the importance of Bristol. This city, at the head of the navigation of the southern Avon, is the "gateway of the west." It has been from early times the wedge between Wales and Cornwall. Its importance grew with trade to and from Ireland and southern France, and later it became the great port for the New World with industries based on its commerce. The passing of the sailing boat, however, changed its fortunes; dock improvements and the refrigerator-boats (for fruit, etc.) are now reorganizing its trade and its industries are still considerable as well as varied. To the south-west is the plain of Somerset with its one-time woollen industry and its now famous cheeses and orchards and successful growing of the sugar beet. The plain is cut off from Bristol by the Mendip hills, an outcrop of Carboniferous limestone rising from beneath the newer rocks.

South of the Pennines, the Red rocks extend eastward in a great sweep through the south of Derbyshire, Warwick, the west of Leicestershire, and the east of Nottingham, their margin being approximately marked by the Avon, flowing south-west, and the Soar and Trent, flowing north-east. South and east of these streams the very similar country is on the Lias clay. Several small coalfields rise through the Red rocks—the largest forms the famous "Black Country," with Birmingham as centre. This midland metropolis draws its population from the three counties of Warwick, Stafford and Worcester at the convergence of which it stands. Its development has been remarkable. It was off the main lines of communication in very early and Roman times and although it was associated with iron-smelting from the late middle ages and its population was increasing, it was still governed as a manor and so had no chartered corporation in the 17th century when, under the Five-Mile Act, dissenters were not allowed to meet in corporate towns; Birmingham in this way became a place of refuge and several families who thus came have provided leaders in scientific, industrial and social life.

With the use of coal its industries enlarged their scope and to-day it is the centre of the motor, rubber and artificial silk industry. Machine tools, wireless apparatus and iron goods of all kinds are made. Around Birmingham are a host of now related towns such as Wolverhampton, Tipton, Walsall, West Bromwich, etc. Some have old industries, *e.g.*, saddlery at Walsall. On the eastern edge of the region is Coventry, also a centre of the motor trade, with recent interests in artificial silk, following old ones in natural silk. To the south-west of the Black Country is the Kidderminster area with its light sandy soils engaged in market gardening for the densely populated industrial areas. In the north-east of Birmingham smaller patches of the Coal Measures appear near Tamworth and Burton, where gypsum beds give the Trent water a special hardness suitable for brewing. Deep shafts have been sunk in many places through the overlying Triassic strata to the coal below, thus extending the mining and manufacturing area beyond the actual outcrop of the Coal Measures. A few small outcrops occur where still more ancient strata have been raised to the surface, as, for instance, in Charnwood forest, where the Archaean rocks, with intrusions of granite, create a patch of highland scenery in the very heart of the English plain; and in the Lickey hills, near Birmingham, where the prominent features are due to volcanic rocks of very ancient date. The midland plain, except in the industrial areas, is fertile and undulating, rich in woods and richer in pasture: the very heart of rural England. Cattle-grazing is the chief farm industry in the west, sheep and horse-rearing in the east; the prevalence of the prefix "Market" in the names of the rural towns is noticeable in this respect.

The manufacture of woollen and leather goods is a natural result of the raising of live stock. Leicester, Derby and Nottingham are manufacturing towns of the region. These towns were important in the middle ages. Nottingham, an old market centre at a river crossing, now manufactures machinery, motor cars, hosiery and cotton goods. Leicester is the great centre of the woollen hosiery trade—its tradition of woollen manufacture going back to the middle ages. Derby is a great entry to the dales, a railway centre and motor manufacturing town.

The midland plain curves northward between the outcrop of Magnesian limestone on the west and the Oolitic heights on the east. It sinks lowest where the estuary of the Humber gathers in its main tributaries, and the greater part of the surface is covered with recent alluvial deposits. The Trent runs north in the southern half of this plain, the Ouse runs south through the northern half, which is known as the Vale of York, lying low between the Pennine heights on the west and the Yorkshire moors on the east. The central position of York in the north made it the capital of Roman Britain in ancient times, and an important railway junction in our own.

The great fault line of the Humber brings the sea nearest to England's manufacturing midlands. Holderness is growing southward into the Humber estuary, but its eastern coast is being rapidly denuded by the sea. The sheltered harbour of Hull, the meeting place of traffic by river and sea, is an important port. On the opposite side of the estuary is Grimsby, importing timber and exporting coal, but best known as the great fishing focus of England. Railways transport the catch in every direction.

The Eastern Area.—Five natural regions may be distinguished in Eastern England, by no means so sharply marked off as those of the west. The first is the Jurassic belt, sweeping along the border of the Triassic plain from the south coast at the mouth of the Exe to the east coast at the mouth of the Tees. This is closely followed on the south-east by the Chalk country, occupying the whole of the rest of England except where the Tertiary Basins of London and Hampshire cover it, where the depression of the Fenland carries it out of sight, and where the lower rocks of the Weald break through it. Thus the chalk appears to run in four diverging fingers from the centre on Salisbury plain, other formations lying wedge-like between them. The Mesozoic rocks of the south rest upon a mass of Palaeozoic rocks, which lies at no very great depth beneath the surface of the anticlinal axis running from the Bristol channel to the Strait of Dover. This is shown by the discovery of Coal Measures, with workable coal seams, at and near Dover.

Eastern England is built up of parallel outcrops, the edges of the harder rocks forming escarpments, the sheets of clay forming plains. The rivers exhibit a remarkably close relation to the geological structure, and thus contrast with the rivers of the West. The Thames is the one great river of the region, rising on the Jurassic belt, crossing the Chalk country, and finishing its course in the Tertiary London basin, drawing its tributaries from north and south. The other rivers are shorter, and flow either to the North sea on the east, or to the English channel on the south.

The Eastern Area is the richest part of England agriculturally and is the part most accessible to the Continent. It is on this plain that the various elements, Celtic, Roman, Saxon, Dane and Norman have been assimilated; it has been a melting-pot of peoples and cultures. The present population is so distributed as to show remarkable dependence on the physical features. The chalk and limestone plateaux are now usually sparsely inhabited and the villages of these districts occur grouped together in long strings, either in drift-floored valleys in the calcareous plateaux, or along the exposure of some favoured water-bearing stratum. In almost every case the plain along the foot of an escarpment bears a line of villages and small towns, and on a good map of density of population the lines of the geological map may be readily discerned.

The Jurassic Belt.—The Jurassic belt is occupied by the counties of Gloucester, Oxford, Buckingham, Bedford, Northampton, Huntingdon, Rutland, Lincoln and the North Riding of Yorkshire. The rocks of the belt may be divided into two main groups: the Lias beds, which come next to the Triassic plain, and the Oolitic beds. Each group is made up of an alternation of soft marls or clays and hard limestones or sandstones. The low escarpments of the harder beds of the Lias run along the right bank of the Trent in its northward course to the Humber, and similarly direct the course of the Avon southward to the Severn. The great feature of the region is the long line of the Oolitic escarpment,

formed in different places by the edges of different beds of rock. The escarpment runs north from Portland island on the English channel, curves north-eastward as the Cotswold hills, rising abruptly from the Severn plain to heights of over 1,000 ft.; it sinks to insignificance in the Midland counties, is again clearly marked in Lincolnshire, and rises in the North Yorkshire moors to its maximum height of over 1,500 ft. Steep towards the west, where it overlooks the low Lias plain as the Oolitic escarpment, the land falls very gently in slopes of Oxford Clay towards the Cretaceous escarpments on the south and east. Throughout its whole extent it yields valuable building-stone. The Lias plain is rich grazing country, the Oxford Clay forms valuable agricultural land, yielding heavy crops of wheat. The towns of the belt are comparatively small, and the favourite site is on the Lias plain below the great escarpment. They are for the most part typical rural market-towns, the manufactures, where such exist, being usually of agricultural machinery or woollen and leather goods. Bath, Gloucester, Oxford, Northampton, Bedford, Rugby, Lincoln and Scarborough are amongst the chief. These towns of old standing retain in many ways something of the life of England before the industrial revolution. Many of them, particularly Oxford and Bath, have been famous for centuries and retain respectively traditions of mediaeval and 18th century England. Lincoln, like Gloucester, is a Roman station and ecclesiastical centre, retaining an importance at the present time as an administrative centre and market town with good railway connections. North of the gap in the low escarpment in which the town of Lincoln centres, a close fringe of villages borders the escarpment on the west; and throughout the entire Jurassic belt the alternations of clay and hard rock are reflected in the grouping of population.
